Countries face different degrees of resource development, of government control, and of private sector participation. These dimensions define a spectrum of country situations that goes from the accumulated conditions of poverty and underdevelopment seen in low-income countries, to the emerging conditions most notably seen in middle-income countries (Table 3.6.2). This chapter focuses on eight critical issues along this spectrum:

1. Health reform with special emphasis on structural reform and decentralization
2. Tools for policymaking—burden of disease, national health accounts, and performance assessment
3. Financing healthcare—sector-wide approaches (SWAps), health insurance and UHC
4. Human resources for health
5. Public–private contracting
6. Equity in health
7. International agencies and public–private partnerships
8. Health research.

Health reform

The rapid rise of non-communicable diseases, the advances in health technologies, the escalating cost of healthcare, and the increasing demands and expectations of populations are leading governments, both in developed and developing countries, to undertake reforms of the health sector.

Structural reform

Health sector reform has been defined as the sustained and purposeful change to improve efficiency, equity, and effectiveness of the health sector (Berman and Bossert 2000; Roberts et al. 2003). Reforms have also been equated with comprehensive and integral change at the systemic, programmatic, organizational, and instrumental levels of the health system (Frenk 1994; González-Block 1997).

At the *systemic* level, changes such as the universalization of access to services, new financing arrangements, and the separation of stewardship and delivery functions have been critical. In turn, reforms at the *programmatic* level may include the definition of specific service

Table 3.6.2 Challenges facing health systems in developing countries, by population and institutional components

Component	Type of challenge	
	Accumulated	Emerging
Population	• Epidemiological backlog:	• New pressure:
	• Common infections	• Non-communicable diseases
	• Malnutrition	• Injuries
	• Reproductive health problems	• Emerging infections
	• Health gap	• Changes in demand patterns
	• Inequity	• Political pressures
Institutions	• Insufficient coverage	• Cost escalation
	• Poor technical quality	• Inadequate incentives
	• Allocational inefficiency	• Financial insecurity
	• Inadequate patient referral	• Patient dissatisfaction
	• Deficient management of institutions	• Deficient management of the system

rights and predefined packages of interventions through explicit choices based on a calculus of benefits and costs. Changes at the *organizational* level may involve introducing quality improvement strategies, increasing provider choice, and implementing provider payment mechanisms to promote quality, safety, and efficiency. At the *instrumental* level, reforms may imply increasing reliance on research, evaluation, and monitoring mechanisms, as well as incentives for human resource and technology development.

Health reforms require the development of monitoring mechanisms to ensure the attainment of objectives within different time spans. Such mechanisms should pay attention both to the technical and the ethical components of health reforms. A number of technical areas for monitoring and decision-making have been identified. These areas include effective coverage, general

level and distribution of health conditions, general level and distribution of responsiveness, and fair financing (see later in ‘Health system performance assessment’) (WHO 2000). This framework was successfully used for monitoring and evaluation purposes at the subnational level in the reform of the Mexican health system aiming towards UHC (Frenk et al. 2006).

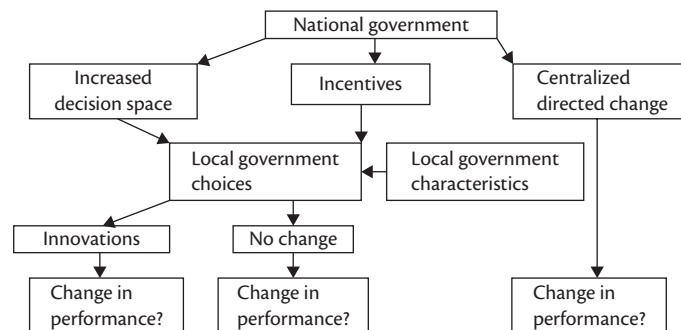

The ethical monitoring of health sector reforms has been enabled through a set of benchmarks of fairness (Daniels et al. 1996). These benchmarks identify and measure the degree of fairness of health systems and of the different objectives pursued by health reforms and has been tested in several developing countries with some success (Daniels et al. 2005).

Decentralization

The decentralization of the planning and management of health services from national authorities to provincial governments is a common feature of structural reforms. However, we are witnessing new trends towards recentralizing services, due both to an assessment of past strategies but more importantly as a result of scaling-up efforts for disease control.

Especially in large countries with dispersed populations, governments cannot efficiently manage the delivery of healthcare from their central offices. In a decentralized system, the central Ministry of Health can set national goals and targets, establish performance-based incentives and monitor their attainment, while devolving the responsibility for detailed management of programmes and services to local authorities. Such arrangements promise improved allocative and technical efficiency, organizational innovation to meet local needs, improved service quality as well as greater equity, together with transparency, accountability, and legitimacy for the health sector as a whole. Three questions are critical to assess the effectiveness of decentralization: (1) the amount of choice that is transferred from central institutions to institutions at the periphery of health systems, (2) what choices local officials make with their increased discretion, and (3) what effect these choices have on the performance of the health system; see Fig. 3.6.2 and Table 3.6.3 (Bossert 1998).

Decentralization entails the establishment of principal–agent relationships, whereby the principal transfers responsibilities but tries to maintain overall control, for example, on the kind of services provided, their quality, and the equity attained (Bossert 1998). Information, assessment, and monitoring instruments are therefore critical for the success of decentralization reforms.

Economic theories based on the choice that consumers have on the consumption of public resources have been useful to understand decentralization in developed countries. However, under conditions of meagre resources there is less local political and economic competition. More important perhaps is the reliance on trusted institutions at the local level and the strengthening of their capacity to ensure common interests across the multiple

actors and often multiple principals that exert influence on health service providers (Gilson 2003).

Decentralization has not been without its critics, arguing that it has been often imposed upon local governments as a means of reducing central government obligations (Ugalde and Homedes 2006). The assessment of the effects of decentralization is now leading to recentralize a number of health functions such as public health surveillance in Mexico. Of greater significance for recentralization, however, is the increased funding by national governments as part of efforts towards UHC as well as by global health initiatives for disease control programmes such as malaria and HIV/AIDS.

Tools for policymaking

Policymaking in developing countries has not always been guided by the best available evidence. In the immediate post-independence period, some developing countries copied models of health services in developed countries with particular emphasis on specialized curative care and the construction of large tertiary hospitals. The high cost of maintaining such establishments often distorted the national health budget, leaving very little resources for supporting less expensive but highly effective community-based services. Because of severe resource constraints, developing countries should set clear priorities and adopt policies that help achieve maximum improvement in health in return for minimum expenditure. This is particularly the case as governments strive to attain UHC of a package of cost-effective interventions.

The establishment of priority lists of disease conditions and interventions was relatively easy in the traditional epidemiological situation where a few major conditions, mainly acute infectious diseases, accounted for a high proportion of deaths. In such situations one could rank priorities by considering the mortality rates from specific acute infectious diseases or the prevalence of chronic disabling diseases like onchocerciasis, a blinding disease. The process of priority setting has become more complex with the epidemiological transition, the increasing differentiation of health systems—including community participation—and the rising demands for equitable coverage.

Efficient decision-making for the allocation of scarce resources for health interventions requires setting priorities in terms of a wide range of considerations (Musgrove 1999; Gericke et al. 2005), to include: (1) the potential health impact and cost of interventions, (2) the ‘public good’ character of interventions as well as their externalities and their consequence for catastrophic expenditure in the absence of public interventions, (3) anti-poverty and equity considerations, and (4) the capacity of health systems to implement new interventions. This process should also consider the establishment of fair procedures for the definition of priorities, with the inclusion of the voice of patients and the community (Daniels 2008).

Burden of disease and priority setting

Health measures are critical for policymaking, in general, and for priority setting, in particular. One of the most widely applied indexes used to measure health needs is disability-adjusted life years (DALYs), which combines losses from premature death and from disability (Murray 1994a, 1994c).

The most common use of the DALY is simply to rank diseases and conditions by the burden of disease (the sum of healthy life years lost and years lived with disability) that they contribute, thus highlighting their relative importance for population health. The DALY is also being used to measure the burden of disease attributable to specific risk factors such as tobacco and obesity. On the basis of such measures, DALYs have been used to assess the contribution of specific risks and risk factors to the disease burden and the impact of major control programmes as well as to estimate cost-effectiveness of interventions by comparing the cost of averting a DALY across them. In its *World Health Report 2000*, the WHO published data on healthy life expectancy (HALE), which is defined as the average number of years that a person can expect to live in 'full health' by taking into account years lived in less than full health due to disease and/or injury. The most recent global measurement of disease burden was undertaken in 2010 by the Institute of Health Metrics and Evaluation, demonstrating the global rise in non-communicable diseases from 43 per cent of total DALYs for 1990 to 54 per cent for 2010 (Murray et al. 2012).

The DALY approach has been critiqued by several authors with respect to technical, methodological, and conceptual issues (Schneider 2001). The data required to estimate the DALY is extensive and is not always available to the extent necessary or with the required quality in developing countries. This has led to the use of questionable assumptions, such as the use of data for non-representative population segments. Another difficulty with the DALY is the combination of death and disability measures under the assumption that these phenomena lie on the same continuum along time (Anand and Hanson 1997).

Most critique of the DALY has centred on the large number of value-based judgements necessary to assign unequal age weights, to estimate the discounting of future health years, as well as to establish the disability weights (Anand and Hanson 1997). Furthermore, disability is quantified with respect to the limitation that diseases impose on individual functionality and does not consider pain and suffering.

The DALY is proving a useful tool but more work is required to refine and simplify it. Under the guidance of WHO, low- and middle-income countries are striving to improve the quality of data collection so as to improve the accuracy of national estimates of burden of disease. Some middle-income countries like Sri Lanka, Mexico, and Brazil are already making effective use of these tools (Morrow and Bryant 1995; Hyder et al. 1998). In Tanzania, the burden of disease approach was adapted to prioritize interventions in the rural districts of Morogoro and Rufiji. After a 5-year period of offering a package of essential health services, under-5 mortality rates had declined by 40 per cent, to less than 100 deaths per 1000 live births, in contrast with the child mortality rate for the country as a whole which remained in 160 deaths during the period of the intervention (de Savigny et al. 2004).

The public good character of interventions offers another criterion for priority setting. Public investment will be justified if the interventions do not have sufficient supply or demand. Such is the case for vector control or environmental risk surveillance. However, even if there is some private supply and demand, the public intervention would be justified if it can be demonstrated that enlarging services would benefit an even wider population beyond that which is consuming the service directly. Such is the

case of immunizations, where individual consumption offers herd immunity to populations at large.

The risk by the poor or the near-poor of incurring catastrophic expenditures when seeking healthcare or as a result of disability to work is in itself a reason to invest public resources. Indeed, in Mexico, around 3 million households suffered impoverishing or catastrophic health expenditures annually in the early 2000s, a situation that led the government to implement the programme *Seguro Popular* (Popular Health Insurance) as a means of achieving UHC with financial protection, a goal that was achieved in 2012 (Knaul et al. 2012).

The condition of poverty of specific population groups is in itself an important criterion to consider for allocating resources on a priority basis. However, poverty in itself is not a reason to provide services indiscriminately, as scarce resources would not be used efficiently in the fight against poverty. This is why it is ethically acceptable to provide a package of highly cost-effective services for the poor, so long as the package is also acceptable to the poor themselves.

The criteria thus far considered for prioritizing public investments in health interventions can be summarized in Fig. 3.6.3, which suggests that investments should be spent on public goods only when they are cost-effective and when they have inadequate private supply and demand. Interventions that particularly benefit the poor should also be prioritized, as should those threatening with catastrophic health expenditure. Vertical and horizontal equity will not always be compatible with cost-effectiveness, leaving decision-making open to political criteria (Musgrove 1999).

The setting of priorities to invest in specific interventions should also consider the capacity of the health systems to formulate appropriate programmes and to deliver on the ground. Assessing health system capacity is today paramount, as new interventions are being scaled-up for the control of malaria, TB, and HIV/AIDS, among other diseases. These interventions require human, technical, and material resources that are often lacking. Four dimensions have been proposed for the assessment of the organizational and economic context (Gerické et al. 2005): (1) technical characteristics of interventions, (2) the logistical and delivery requirements, (3) the requirements stemming from governmental regulation, and (4) the characteristics of demand and utilization.

Technical characteristics of interventions include the basic design of products and technologies, such as stability and shelf-life. Product standardization is critical as similar interventions will be more easily implemented. Costs that are incurred during implementation but that may not have been considered in cost-effectiveness analysis include safety monitoring, supervision, storage, and regular, on-time delivery. Regulatory costs can be considerable, such as accreditation of health providers and facilities to ensure service quality as well as measures to curb corruption. Often the costs necessary to ensure compliance and coercion are not considered when formulating new programmes, leading to low enforcement of measures to increase quality and efficiency. Finally, priority setting should consider the ease of use of technologies by the population at large, including the extent to which health education is required to ensure demand and compliance. Ease of use may also be related to the proliferation of black markets and forgery for which countermeasures should be implemented.

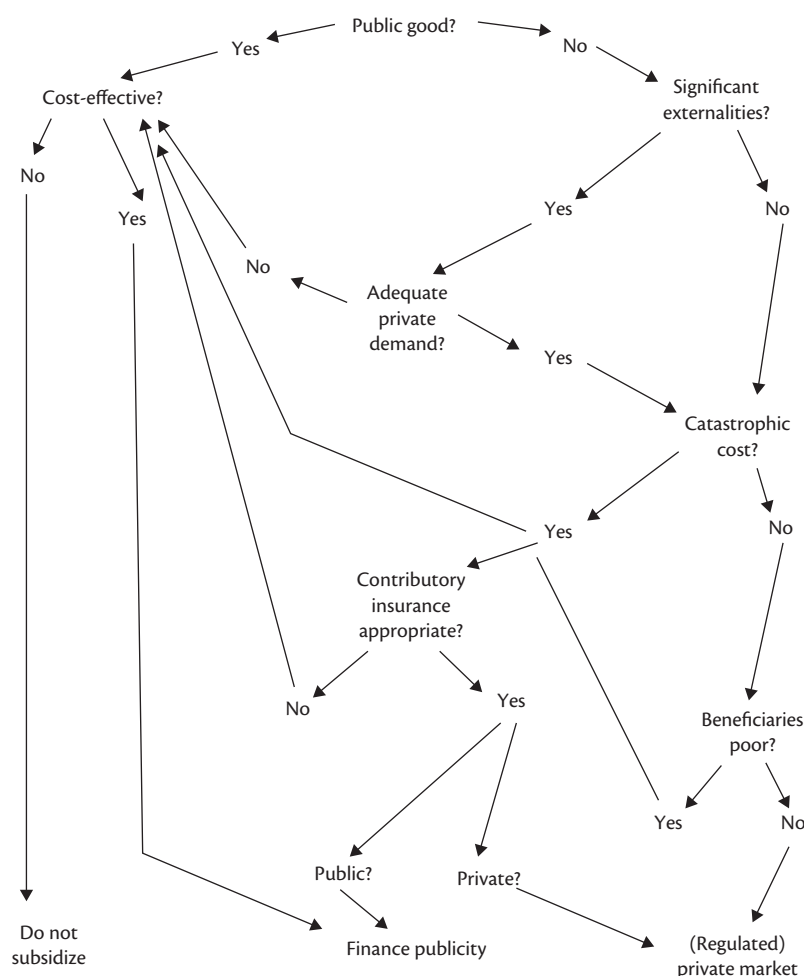

Fig. 3.6.3 Decision tree for assessing public investments in health.

National health accounts

In the past, policymakers concentrated mainly on spending within the public sector, ignoring private spending through insurance, corporate arrangements, and employees' schemes, and out-of-pocket spending. Furthermore, spending within the public sector lacked clear indicators on resource flows, thus contributing to growing inequity and inefficiency. Policymakers now obtain a more comprehensive view of health expenditures thanks to the use of national health accounts developed through a uniform methodology. These analyses integrate health spending from all sources—public and private, corporate, and personal, national and international—within comprehensive accounts. National health accounts can affect the choices made within the public sector but also influence the role of public agencies in providing guidelines to the private sector and to communities regarding the most cost-effective uses of their investments and expenditures.

Health accounts consist of a basic matrix, where the columns list all sources of health spending—public (taxation and national social insurance), and private sources including employment-based schemes, privately financed insurance, and out-of-pocket expenditure. The rows of the matrix show the distribution of expenditure

for personal healthcare, public health, and environmental sanitation services, and administration. Disaggregating the items in the columns and rows generates more elaborate analyses, providing more detailed information about sources and spending. Thus, the analyses could show variations over time, by geography, by population subgroups, or any other variable that is relevant to policy-making (Berman 1997; WHO 2003). Today, health accounts are being prepared not only at the national level but also by specific programmes such as HIV/AIDS and reproductive health.

Health system performance assessment

The *World Health Report 2000* offered a comprehensive methodology and reported results to assess the overall performance of health systems in terms of health gain, responsiveness to the legitimate expectations of the population, and fairness of financing (WHO 2000). The degree to which these outcomes are achieved depends on how well the basic health system functions of stewardship, financing, resource generation, and service provision are carried out (Fig. 3.6.4). The three health system outcomes were assessed in terms of equity and efficiency, except financial fairness for which only equity is appropriate. Health gain was measured through

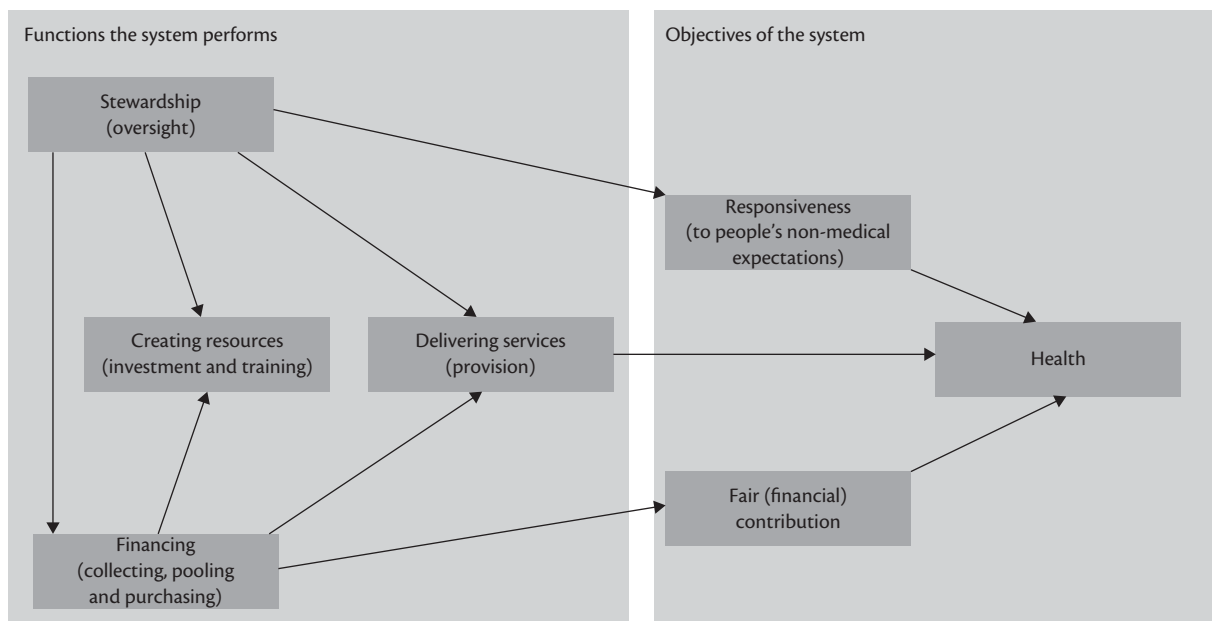

Fig. 3.6.4 Functions and objectives for the measurement of health system performance.

healthy life expectancy, already described under the priority setting section above. The methodology enabled the measurement of each health system goal separately as well as through a combined indicator. All WHO member countries were then ranked as a means of highlighting the benefits and limitations of health system designs as well as to promote analysis and improvements.

Performance assessment can support policymaking in monitoring and evaluating attainment of critical outcomes and the efficiency of the health system in a way that allows comparison over time and across systems. Performance assessment enables the measurement of the relationship between design of health systems and outcomes and the dissemination of evidence on the benefits of diverse health system designs and reforms. The use of a widely accepted, comparative method was intended to feedback the policy debate as well as to empower the public with information relevant to their well-being (Murray and Evans 2003).

The methodology for performance assessment was widely debated by academics and governments and the Executive Board of WHO called for the establishment of a Scientific Peer Review Group (107th Session, EB107.R8, 15–22 January 2001). It was argued that intersectoral action for health was not subject to monitoring, focusing only on those functions and outcomes that are more directly under the control of ministries of health. Given that health sector policymaking may be the result of actions taken in an indefinite past, it will not be clear whose actions are being assessed at any given point in time.

Perhaps most controversial was the lack of consensus on the weighting that was given to each of the three separate dimensions of performance, where following a Web survey, health gain was assigned 50 per cent and responsiveness and financial protection 25 per cent each. Data used for the 2000 report was also faulted for excessive use and lack of clarity of the estimations that were necessary, given poor data quality and availability in many countries.

Performance assessment has been widely endorsed as a tool for policymaking for developing countries and, as mentioned earlier, was the basis for the monitoring of health sector reform in Mexico. WHO has called for improvements (WHO 2007), among them paying more attention to the broader health system as well as to the relationship between measured outcomes and health system functions. The Expanded Chronic Care Model could point towards new approaches to measure the contribution of the community, health policy and health systems towards more performing health strategies that take into account critical actors and multilevel chains of causation (Barr et al. 2003). Inequality should be more broadly measured, to include both health as well as socioeconomic inequality. In this respect, the Commission on Social Determinants for Health provided ample evidence and methods on how to integrate equity in health policy (Irwin et al. 2006). Subnational analyses should be carried out to identify success and limitations that can be more easily disseminated at the national level. Implementation research is being increasingly funded as a way to identify process bottlenecks and access barriers hampering the performance of policies and programmes (WHO 2011).

WHO also called to strengthen national health information systems as tools for performance assessment through the development of a broad range of health metrics. Mexico demonstrates how middle-income countries with reasonably developed information systems can make use of data for health system performance assessment. From 2000 to 2006, a set of health conditions and service benchmarks were systematically measured at state level and disseminated at yearly intervals. Evidence indicates that state authorities agreed on the quality and relevance of these measures and have accepted on this basis to be systematically monitored by federal health authorities and interested actors. Systematic monitoring has also led to the development of effective coverage measures, defined as the proportion of potential health gain

that could be delivered by the health system to that which is actually delivered (Lozano et al. 2006). A total of 14 health interventions have been monitored and overall effective coverage assessed through a comprehensive indicator. Overall coverage ranged from 54 per cent in Chiapas, a poor state, to 65.1 per cent in Mexico's capital. These findings suggest that basic health interventions are much more equitably distributed in Mexico with respect to other health indicators.

Financing and contracting for healthcare

During the 1980s, international financing agencies restrained public investments in health as part of structural adjustment programmes with negative consequences for health systems. These policies have now been reversed as the United Nations (UN) enshrined the MDGs with important health targets for maternal and child health as well as HIV/AIDS, TB, and malaria among other epidemic diseases. MDGs served as a basis on which to mobilize national and international resources (World Bank IMF Development Committee 2003). Also, the Commission on Macroeconomics and Health, convened by WHO under the leadership of Jeffrey Sachs, produced analytical data advocating massive investments in health as a means of spurring economic growth (Commission on Macroeconomics and Health 2001). The Monterrey Consensus agreed at the 2002 UN Financing for Development Conference intends to double the level of international aid through an additional US\$20 billion per annum to enable poor countries to achieve the MDGs (Sachs 2004).

Scaling up health financing in poor countries

Government capacity is now being revamped in many countries to ensure that massive scaling-up of health interventions can be undertaken under conditions of efficiency and equity. However, before interventions can be scaled up, low-income countries under stress—essentially countries with low governance—will have to strengthen their institutional capacity to ensure efficient and equitable resource allocation. It has also been recommended that resources be allocated to interventions whose delivery is least covered by the market so as to increase the impact of government services (Filmer et al. 2000).

The IMF and World Bank estimate that large increases in aid (a doubling or more of current flows) could be used effectively in countries with good governance such as Bangladesh, India, Indonesia, Pakistan, and Vietnam, and in some sub-Saharan African countries, such as Ethiopia. These countries have a combination of good policies and prospects for further improvement, large unmet needs relative to the MDG targets, and relatively low levels of aid dependence. Sub-Saharan African countries considered to have good governance such as Burkina Faso, Mozambique, Tanzania, and Uganda could also use additional aid productively to supplement the sizable flows they already receive—an increase of about 60 per cent on average in the medium term.

Evidence suggests that international short-term health aid is indeed supporting economic growth, regardless of the strength of governments (Clemens et al. 2004). Effective low-cost health interventions have also been effectively put in place and sustained in countries with weak governments or even under conflict situations (Medlin et al. 2006; Center for Global Development 2007).

Aid harmonization and sector-wide approaches

Donors and recipient countries have achieved a high degree of consensus regarding the provision of international aid. The Paris Aid Harmonization Declaration and Principles commits partners to recognize developing country ownership of development policies, and the alignment of donors with country strategies, institutions, and procedures. This implies a commitment by donors to support capacity strengthening of government procedures, rather than supporting specific aid delivery mechanisms. In terms of harmonization, the Paris declarations commit donors to a more harmonized, transparent, and collectively effective giving through common arrangements and simplified procedures. Complementarity is to be sought through a more effective division of labour while greater attention should be paid to aid provision in fragile states. Aid policies should be devised so that they can be managed by results, furthering collaborative behaviour and through mutual accountability (Paris Declaration 2005).

Donor harmonization in health has also been pursued through sector-wide approaches (SWAs), a process whereby funding for the sector—whether internal or from donors—supports a single policy and expenditure programme, under government leadership, and adopting common approaches across the sector. It is generally accompanied by efforts to strengthen government procedures for disbursement and accountability. A SWA should ideally involve broad stakeholder consultation in the design of a coherent sector programme at micro, meso, and macro levels, and strong coordination among donors and between donors and government (Brown et al. 2001).

Universal health coverage

Health system financing has proven to be double-edged, mobilizing increasing amounts of resources for health but also driving millions of families into hardship or poverty when resource mobilization forces families to pay excessive amounts through out-of-pocket payments, chiefly for essential medicines and curative care. WHO proposed governments in its 2005 report *Health Systems Financing. The Path to Universal Coverage* to critically analyse how the health system is financed, how to protect people from the financial consequences of ill health, and how to encourage the optimum use of available resources (WHO 2005). Today, many developing countries are proposing to achieve UHC in the short to medium term, broadly understood as fair financing of essential healthcare through prepayment of health services and broad-based resource pooling. Two criteria are key to assess if a health system is offering UHC: financial protection for all from the costs of healthcare and effective access to needed healthcare for all citizens (McIntyre and Mills 2012). To attain this, UHC requires effective resource mobilization as well as reducing out-of-pocket payments in the context of more efficient health services. For health systems to function equitably towards UHC, financing should balance the depth, breadth, and proportion of health costs covered (Chua and Cheah 2012).

Community health insurance has been proposed to improve access by rural and informal sector workers to needed healthcare. Macro-level cross-country analyses give empirical support to the hypothesis that risk-sharing in health financing matters in terms of its impact on both the level and distribution of health,

financial fairness, and responsiveness indicators (Preker et al. 2003; Alliance HPSR 2004).

Five key policies are available to governments to improve the effectiveness and sustainability of community financing schemes:

- ◆ Increased and well-targeted subsidies to pay for the premiums of low-income populations.
- ◆ Insurance to protect against expenditure fluctuations and re-insurance to enlarge the effective size of small risk pools.
- ◆ Effective prevention and case management techniques to limit expenditure fluctuations.
- ◆ Technical support to strengthen the management capacity of local schemes.
- ◆ Establishment and strengthening of links with the formal financing and provider networks.

Middle-income countries with segmented health systems face particular challenges to extend insurance coverage to a rising population employed in the informal sector. China has made impressive progress towards UHC as it increased coverage to health insurance schemes for its population from 29.7 per cent in 2003 to 90 per cent at the end of 2010. Behind this rapid expansion are two insurance schemes: the New Cooperative Medical Scheme for the Rural Population (NCMS) and the Urban Resident Basic Health Insurance (URBMI) (Tang et al. 2012). However, it is of concern that this rapid expansion has also been accompanied by cost explosion at an annual rate of 17 per cent in the past two decades. The total health expenditure increased from 74.7 billion Chinese Yuan in 1990 to 1998 billion Yuan in 2010, while average health expenditure per capital reached 1490.1 Yuan per person in 2010, rising from only 65.4 Yuan per person in 1990 (Tang et al. 2012).

New schemes have been implemented aiming at universal access to care through voluntary, government-subsidized schemes such as *Seguro Popular* in Mexico. Short-term assessments point to success in improving access to health services and reducing the prevalence of catastrophic and impoverishing health expenditures, especially for the poor, as well as improvements in access to priority interventions (Gakidou et al. 2006; King et al. 2009). However, research also points to opportunities to diversify the health provider network and to encourage more effective, equitable and responsive health services (Knaul et al. 2012).

The effects of voluntary insurance schemes upon formal sector employment need to be addressed to ensure that morally just and cost-effective schemes also fuel the economy and are a step towards fully integrated, equitable publicly financed health systems. Using a robust database, Wagstaff and colleagues were able to establish for Thailand that universal coverage had a mixed effect, encouraging employment generally but discouraging formal sector employment among married men, yet not in other groups (Wagstaff and Wanwiphang 2012a). UHC had a positive impact on economic development through reducing the likelihood of people reporting themselves to be too sick to work (Wagstaff and Wanwiphang 2012b). These findings point to the importance of envisioning UHC schemes as transitory arrangements towards universal health systems.

Human resources for health

The WHO has estimated that, to meet the ambitious targets of the MDGs, health services in Africa will need to train and retain an

extra 1 million health workers by 2010, chiefly nurses and other classes of health workers who constitute the bulk of the workforce. Health systems in poor countries face a very low-density health workforce, compounded by poor skill mix and inadequate investment. In addition, migration of trained human resources to more developed countries is becoming an ever more important issue.

Mass migration of health personnel is often a symptom of the 'sick system syndrome', in which many essential components of healthcare services are malfunctioning and mismanaged. Policies on migration must tackle the 'pull factors', which induce trained personnel to seek better living conditions abroad, as well as the 'push factors', which make disaffected and frustrated health workers seek employment elsewhere. Health challenges, such as the HIV/AIDS epidemic, impose additional pressures on health workers in their workplaces and at home, exposing them to contagious hazards, which adversely affect the morbidity and mortality of the workforce. The 'anchor factors' which encourage workers to remain in public service are important too. These should include financial incentives as well as well-designed training programmes that increase workers' skill and competence, boost their morale, increase their job satisfaction, and improve the performance of services (Lucas 2005).

Effective policymaking for human resources has to overcome the low attention that is given by both national governments and international agencies. Fiscal discipline depends on restriction of staff numbers and compensation levels, with staff salaries now consuming 60–80 per cent of diminished public budgets in the health sector. There is also a lack of coherent and integrated investment strategies to strengthen the workforce, resulting in an overemphasis on workshops and training sessions that have an unclear effect. Such constraints operate in a context of health-sector and civil-service reforms that have altered the work environment through expansion of the private sector, downsizing, and decentralization in the public sector. Public–private contracting has thus been increasingly sought after as a means of addressing multiple constraints.

An informal global network of health leaders supported by the Rockefeller Foundation's Joint Learning Initiative has proposed four immediate steps towards a reinvigorated human resources for health policy (Joint Learning Initiative 2004):

- ◆ Large-scale advocacy to achieve heightened political awareness within countries and globally, leading to a social mobilization to respond to the crisis in the short term.
- ◆ Improve information and develop a commonly accepted framework of ideas, terms, and relations to guide analysis for policy formulation, particularly on the mobility of health professionals and the relations between health equity and human resources.
- ◆ Learn from history and identify success stories demonstrating the goodwill and commitment of health workers in spite of adverse conditions. Lessons from BRAC in Bangladesh are highlighted, employing over 30,000 village health workers to raise awareness of health issues among the rural poor.
- ◆ Address the supply, demand, and mobility of personnel, linking across training and education, health systems, and labour markets to develop a system that ensures continuity of policies over time. This includes a process of addressing low wages, as well as creating an incentive structure that supports providers over the course of their working lives.

International debate around the responsibilities of all actors has also produced an interesting range of proposals, including ethical recruitment guidelines and financial compensation for exporting countries (Brush et al. 2004). Diagnostic approaches are required to inform evidence-based action: identify signs and causes of the 'sick system syndrome'. These should lead to the development and adoption of policies on human resources which are relevant, affordable, and sustainable, and are realistic about migration of trained staff (Lucas 2005).

Policymaking and the public-private mix

The private health sector may be defined as comprising all providers who exist outside the public sector, whether their orientation is philanthropic or commercial, and whose aim is to treat illness or prevent disease (Mills et al. 2002). However, the public and private sectors are highly related as public sector workers often have a private practice and many public facilities offer private wards or services or operate in such a manner that they are indistinguishable from profit-seeking private providers (Meng et al. 2004).

As stated previously, even in developing countries with a widespread public system such as Mexico, catastrophic or impoverishing out-of-pocket health expenditures, which imply an extensive use of private medical services, affect a large proportion of the population (Knaul and Frenk 2005). In these contexts, it is vital to support consumers in their use of health services. Such efforts could stimulate appropriate demand through improving consumer information or could make services or products more affordable. Efforts can also influence the supply of services through creating institutions that give consumers greater authority to challenge care of poor quality (Mills et al. 2002, Söderlund et al. 2003).

Social marketing is an approach to stimulate demand of cost-effective interventions by increasing consumer information and subsidizing access to services. This approach has been particularly used to demand services within the private sector for

reproductive health and basic sanitation. Limitations have been identified with regard to the extent to which social marketing stimulates or rather limits the private sector, the targeting of the poor, and leakage of benefits to the better-off who could afford to pay full price for health services and commodities.

The use of vouchers has been tested on a limited scale as a means of targeting the poor without having to provide a generic subsidy. Protection of patients has also been pursued through the establishment of specialized government agencies to facilitate the settlement of malpractice and negligence, attempting to reduce the costs and negative consequences of litigation (Tena and Sotelo 2005).

Efforts on the supply side to improve the quality and value of private providers have included the promotion of professional training and accreditation as well as giving access to their patients to a limited range of public goods or services as for the treatment of TB (Marek et al. 1999). However, the most important efforts have been in the area of purchasing or contracting of a full range of primary or hospital services for specific population groups. These functions involve the separation of purchasing and provision at the government level and exercising stewardship functions, as already noted at the beginning of this chapter. The main challenge with these approaches lies in the capacity by government to develop contracts, set prices, and monitor and supervise private providers (Slack and Savedoff 2001; Palmer et al. 2003).

Equity in health

Policymakers in most developing countries are aware that poverty and ill health are intertwined and that important differences in health exist both across countries and provinces and across socioeconomic groups (Figs 3.6.5 and 3.6.6). It is now accepted that poverty breeds ill health and that ill health keeps poor people poor (Fig. 3.6.5). The concept of equity in health is based on a fundamental principle: that differences in health that are the result either of the exposure to unhealthy life or working conditions or

limited access to essential health services are morally unacceptable (Whitehead 1990; Dahlgren and Whitehead 1991).

Inequality in the health status of individuals and communities is a global phenomenon. Such disparities have been observed even in the most affluent countries but are most striking in developing countries where the poorest citizens often lack access to the most basic healthcare. Efforts to reduce such disparities have only been partially successful and too little is known on the reasons behind failure (Wagstaff 2002).

Equity can be assessed in three complementary dimensions: in health status of families, communities, and population groups; in allocation of financial, technical, and material resources; and in access to, and utilization of, high-quality services. Attention must be paid to political commitment towards equity and to equitable policy formulation. To this end, information, monitoring, and evaluation for equity should be in place. Each of these dimensions of equity and of their political and policy dimensions are now considered.

The basic dimensions of health equity

Gross inequality in health status is regarded as *prima facie* evidence of inequities in the healthcare system. Significant inequalities in health status are found even in the most affluent developed countries, with long traditions of national health services that are designed to provide universal coverage (Black et al. 1998; Pollock 1999). A consistent finding is the strong association between poverty and poor health as defined by such indicators as the expectation of life, the incidence of acute diseases and injuries, the prevalence of chronic diseases and disabilities, and low access to services (Gwatkin 2000; Wagstaff 2002).

This consistent association of poverty with ill health makes it necessary for health systems to address the needs of the poor, and it strengthens the case in favour of programmes for the alleviation of poverty as important strategies for health promotion. It also draws attention to the influence of factors outside the health sector on health development: the levels of education and especially of girls, which has proven to be among the most powerful factors in reducing infant mortality; access to adequate quantity of safe water and

environmental sanitation; as well as food and nutrition. Lifestyle and human behaviour, including such personal choices like smoking, use of alcohol, sexual behaviour, and physical exercise, also have important effects on health outcomes (Gwatkin 2003).

Equity is also examined in terms of the allocation of resources to different sections of the population. On moral and ethical grounds, the objective of allocative equity is for public resources to be shared out in a fair manner (Taipale 1999). The simplest formula would be a uniform per capita allocation. However, if large differences in health status already exist, an equal allocation would tend to perpetuate the inequalities. It can be argued that it is the responsibility of governments to perform a re-distributive function by allocating resources from the more affluent sector of society to meet the needs of lower-income individuals and families, the so-called vertical equity already mentioned when addressing priority setting.

Another view of equity is that everyone should have an equal opportunity of receiving care. This so-called horizontal equity proposes that individuals in like situations should be treated in like manner. Access is often defined in terms of the availability of services and its geographical coverage but experience has shown that the potential access, i.e. the services are within geographical range, does not necessarily correspond to real access as measured by the utilization of services (Jacobs and Price 2006).

Marked disparities are often found in the geographical distribution of health facilities: between regions, between urban and rural areas, between rural areas and within urban areas (Phillips 1990). The differential ratios of persons per facility—hospital beds, nurses, and doctors—are used to measure the disparities. The distribution of health centres and other institutions in relation to the population—how far people have to travel to reach such facilities—are also used to indicate the uneven distribution of resources.

Political commitment for equity and equitable policy formulation

The political commitment of the government is the essential basis for promoting equity in health (Feacham 2000). The objective of

equity in health fits well with the political philosophy in welfare states that have the clear goal of providing universal coverage of comprehensive healthcare for the entire population 'from the womb to the tomb'. In such countries, the question is not whether the State should embrace equity in health but how to achieve this goal in practice. Many developing countries have adopted more limited but realistic goals of providing universal access to a cost-effective package of services, together with universal financial protection through social health insurance (Frenk et al. 2006). In Mexico, the package of essential health services upon which *Seguro Popular* relied was devised using cost-effectiveness criteria as a priority-setting tool. However, the package was also a means to ensure that all citizens, regardless of their labour or socioeconomic status, have the right to universal access to healthcare. The Mexican model may be seen as reconciling two extremes: the selective, technocratic approach to the distribution of healthcare, which provides practical alternatives but is usually morally neutral, and the rights-based approach, which has a strong value foundation but has lacked operational support (Frenk and Gómez-Dantés 2007).

UHC efforts need to place health equity in the forefront, making it an end in itself and ensuring the most efficient systems are put in place to make cost-effective services available (Reidpath et al. 2012). Furthermore, UHC policy has to be rolled-out with a clear equity goal in mind so as to avoid 'regressive universalization', a paradoxical condition where the better-off would benefit first and could capture a greater proportion of benefits (Gwatkin and Ergo 2011). Research suggests that some countries manage to implement UHC equitably. Thailand implemented a universal coverage for its 47 million uninsured and was able to do so through a resource allocation scheme with strong pro-poor features that ensured equity (Limwattananon et al. 2012). However, effective access to essential health services has to be ensured through culturally appropriate models that ensure that the needs of diverse groups of population are fully met. Political commitment for equity is also required to correct the inequities that result from discrimination on the basis of gender, race, ethnic group, and religion. Often, inequalities in health status reflect the marginalization of disadvantaged groups (Brockerhoff and Hewett 2000). The plight of indigenous populations in the Americas and Australasia is a special case.

In weighing policy options, a good guideline would be to examine critically the expected impact of the selected option on equity. The formulation of health policies has to contend with a variety of pressures including the increasing demands of populations for more services, the desire to achieve maximal improvement in health of the populations served, and the need to contain costs. Reforms of the health sector aim at improving efficiency, effectiveness, cost-effectiveness, and equity. It is not always easy to reconcile these goals. For example, the delivery of care to the populations in remote areas is relatively expensive and less cost-effective than services to dense urban areas. However, in the interest of equity, health services should reach the underserved populations even in remote settings.

The impact of macroeconomic policies on health also deserves attention. For example, under pressure from the international finance agencies, some developing countries undertook Structural Adjustment Programmes (SAP) and markedly reduced public investment in health and other social sectors. UNICEF (2004)

and other agencies drew attention to negative impact of SAP on the health of children. In future, careful analysis and relevant research would be used to design macroeconomic policies that would not harm the health of vulnerable groups. The international community has responded to this problem by adopting policies for alleviating poverty. Debt relief for the poorest nations has been one of the major mechanisms for alleviating poverty.

One aspect of equity is that the government should allocate financial resources fairly to the entire population. A simple demographic formula that allocates funds simply on population size may need to be adjusted to take note of special needs of particular regions; otherwise, the uniform allocation may tend to perpetuate inequalities. Another source of inequity is the degree to which local authorities can raise additional funds through taxation and by retaining user fees (Brikci and Phillips 2007). Again, the fact that the more affluent areas are able to raise much larger funds than the poorer areas may tend to widen the gap in the quantity and quality of healthcare.

Within the health budget, there is the difficult task of allocating resources to the needs of the various groups within the community (Castro-Leal et al. 2000; Makinen et al. 2000). With finite resources, even the most affluent nations have to accept limits to the services that the public sector can provide. Hence, rationing is an inevitable feature of health planning. In the interests of equity and social justice, if economies have to be made, the burden should be fairly shared among various sectors of the community. Quantitative estimates of burden of disease and of the cost-effectiveness of various interventions help to rationalize the selection of priorities (Murray 1994a, 1994b, 1994c; Hyder et al. 1998). But a point is reached at which hard choices cannot be made solely on the basis of objective measurements. At this stage, the debate must include philosophical and ethical considerations about the value of human life (Morrow and Bryant 1995).

The Poverty Reduction Strategy Papers (PRSPs) are a promising avenue to focus policymaking on the poor, although much needs to be done to influence health policymaking through this strategy (Laterveer et al. 2003). The majority of PRSPs lack country-specific data on the distribution and composition of the burden of disease, a clear identification of health system constraints and an assessment of the impact of health services on the population. More importantly, they make little effort to analyse these issues in relation to the poor. Furthermore, only a small group explicitly includes the interests of the poor in health policy design. Attention to policies aiming at enhancing equity in public health spending is even more limited. Few papers that include expenditure proposals also show pro-poor focused health budgets.

Tools are available to trace the extent to which investments at national levels benefit the poor and needy, taking into consideration the effects on income and health and considering the relative size of benefits given the levels of health and income (Gwatkin 2000 and 2003). The better-off in Africa and in India benefit far more than the poor from public spending (Castro Leal et al. 2000). Recent analyses in Mexico suggest that the incidence of health benefits is improving for the poor thanks to financial reforms, although still inequitable (Frenk et al. 2006). However, analysis of a wide range of evidence suggests that tax-based funding distributes health benefits more evenly and targets the poor more effectively than social health insurance (Wagstaff 2007).

New tools are also being developed to forecast demand for global health funding of programmes benefiting the poor (Sekhri 2006). These efforts stem from the realization that the lack of accurate and credible information about the demand for essential health products costs lives. Gaps and weaknesses in demand forecasting result in a mismatch between supply and demand—which in turn leads to both unnecessarily high prices and supply shortages.

Equity information, monitoring, and evaluation

In order to design services that are equitable and to monitor performance of health services, each health authority needs an appropriate management information system which must include measuring inequalities in health status and inequities in access to healthcare. The data collecting instruments must be designed to take note of groups and subgroups especially vulnerable groups whose access to services is restricted by geographical, economic, social, and cultural factors. It should include the usual demographic indicators—age, sex, and marital status, as well as socio-economic indicators—race, ethnic origin, occupation, residence, and other social variables (Rosen 1999).

The health system should include mechanisms for monitoring equity objectively. Interest in measuring equity has generated some useful tools and some valuable experience is accumulating. In the first instance, monitoring equity is the responsibility of health authorities at each level of care. They must build into their service, sensitive indicators that would inform them of their performance with regard to equity and access to care.

In addition to such internal processes, it would be valuable to commission independent reviews of equity within the health system by groups outside the health departments. Another option would be to assign responsibility for a national equity watch to a local non-governmental organization.

International organizations

International organizations, bilateral and multilateral, are influential in developing country policy under many circumstances. A new breed of agencies, development banks, global health programmes (GHPs), and public–private partnerships (PPPs) are also increasing their presence in policy design, implementation and evaluation in low- and middle-income countries, particularly through financing health interventions. Global philanthropic organizations are also playing a major role in the definition of the global health agenda and in the mobilization of financial resources for health. Salient among them is the Bill and Melinda Gates Foundation (*The Lancet* 2009).

UN agencies

WHO is the lead agency for health within the UN system. In recent years, other international agencies have increased their involvement in the health sector. The United Nations Children's Fund (UNICEF) through its child survival programme, provides massive input into the health sector often in collaboration with WHO. With the leadership of James Grant in the 1980s, UNICEF was key in substantially increasing immunization coverage in poor countries. This support flattened out after Grant's period, but was boosted again when UN and private agencies established the innovative Global Alliance for Vaccines and Immunizations (GAVI).

Other UN agencies like the United Nations Fund for Population Action (UNFPA), the International Labor Organisation (ILO), and the Food and Agriculture Organization (FAO) have relevant programmes involving specific aspects of the health sector. The United Nations Development Programme (UNDP) issues a highly influential annual report that includes the Human Development Index, a composite of indicators including key health measures. The International Monetary Fund (IMF) plays a key role in national financing policies. Its Structural Adjustment Programme in the 1980s was widely critiqued—starting with UNICEF—for restraining key public health programmes in poor countries. Through its lending programme, the World Bank represents an important source of external finance for the health sector and has stimulated countries to develop more efficient and cost-effective health programmes.

Generally, these external agencies operate independently of each other at country level but there have been some attempts at coordination and collaboration. UNICEF and WHO have established mechanisms of collaboration including such formal mechanisms as the Task Force for Child Survival. WHO also sometimes executes health programmes on behalf of other external agencies. A more ambitious attempt at interagency collaboration is the UNAIDS programme; six UN agencies jointly manage this programme for the global control of HIV/AIDS epidemic.

Global health programmes and public–private partnerships

There has been a proliferation of GHPs and public–private partnerships, with more than 70 in existence. They account for close to 20 per cent of international aid for health. Examples include Roll Back Malaria (RBM), the Global Alliance for Vaccines and Immunization (GAVI), the International AIDS Vaccine Initiative (IAVI), and the Global Fund for AIDS, TB and Malaria (GFATM). The vast majority focus on communicable diseases—60 per cent of identified GHPs target the big three diseases—HIV/AIDS, TB, and malaria—with HIV/AIDS attracting the most GHPs by some margin. However, almost all the 'most neglected' diseases (such as lymphatic filariasis and leishmaniasis) are now supported by at least one GHP, many of which have been established in recent years. No GHPs address non-communicable diseases or health systems per se.

Africa has the highest number of GHPs per country, followed by Asia (East, South East, and Central). GHPs vary substantially in scale, cost, operational structure, and impact on systems at country level, including research and development as well as technical assistance and service support. GHPs which support improved service access may provide discounted or donated drugs, and give technical assistance. Some GHPs are dedicated to advocacy for increased international and/or national response and resource mobilization. The Global Fund is dedicated to financing for specific disease programmes.

GHPs are generally considered to deliver positive results in the following areas: leverage of additional funds (including from private sector); promotion of global public goods, raising profile of neglected issues, more inclusive governance, enhanced aid effectiveness through pooling of resources, and reduced commodity prices. On the other hand, common criticisms levelled at GHPs are the creation of additional complexity in an international aid system that is already overloaded. For certain GHPs, poorer

countries do not meet eligibility criteria or have the capacity to frame successful proposals. Other limitations include the distortion of national priorities, the provision of international aid made ad hoc and less predictable, dysfunctional national coordination mechanisms, the establishment of parallel structures or additional burden on existing national systems, displacement of existing government services, disproportionate demands on time of Ministers and senior officials, national strategic planning and budgeting processes undermined, and diminished political accountability (Buse and Waxman 2001; Widdus 2003).

Health research

In many respects, health policy in developing countries is all about the encouragement of innovation and the scaling-up of life-saving technologies and system processes. As highlighted previously, increased access to knowledge and technology has accounted for perhaps as much as two-thirds of the 2 per cent per year rate of decline in under-5 mortality rate (Jamison 2006). Furthermore, there is increasing realization that research and evaluation can play a valuable role for shared learning from health sector reforms (González-Block 1997).

The case has been made that it is as unethical to introduce health reforms that have not been previously validated or thoroughly analysed as it is to introduce untested medical technology into healthcare. Indeed, both can have important health consequences, even more so population interventions that are adopted on a massive scale (Daniels 2006). WHO has recognized that 'Ignoring research evidence is harmful to individuals and populations, and wastes resources' (WHO 2004).

Health research—including health policy and systems research—thus plays a double role in policymaking. As a core function of health systems, research contributes knowledge as one of the most critical resources for healthcare. Formulating and implementing health research policy is therefore a key component of health policy overall. On the other hand, research on health policy and systems contributes knowledge and applications to improve the way that societies organize themselves to respond to health problems and challenges (Alliance HPSR 2004). Such knowledge is today one of the scarce resources limiting health system performance.

Health research systems and policy

WHO together with the Council on Health Research for Development and the Global Forum for Health Research advocate health research policy through the development of health research systems at national level and through a well-structured international architecture (Pang et al. 2003). Health research systems should be strengthened by building relevant capacity, developing capable leadership, providing essential monitoring and evaluation tools, improving capacity for ethical review of research, and putting in place necessary ethical standards and regulations for population health, health services, and clinical research. Health systems should further promote access to reliable, relevant, and up-to-date evidence on the effects of interventions, based on systematic reviews of the totality of available research findings (WHO 2004).

Health research systems provide a promising opportunity to link knowledge generation with practical concerns to improve

health and health equity. Pioneer health research systems from Canada and the UK show that academic centres and service agencies can be related in ways that encourage the utilization of research (Lomas 2000; Kogan et al. 2006), such as networking between existing stakeholders (Department of Health 2006). A key issue is the balance between funding research through independent research councils that have science-led priorities and funding research in response to the priorities of healthcare systems.

New science frameworks are solving these dilemmas through positing a move from the traditional discipline-centred mode of knowledge production (characterized as Mode 1), towards a broader conception (Mode 2) where knowledge is generated through a context of application and thus addresses problems identified through continual negotiation between actors from a variety of settings (Gibbons et al. 1994). Another conceptualization, Pasteur's Quadrant, suggests how types of research can be considered according to two dimensions, a quest for understanding and considerations of use. This gives rise to three categories of research depending on the extent to which general understanding arises in the process of solving specific problems, or whether only pure knowledge or pure application is generated (Stokes 1997).

Evidence-based policymaking

New science frameworks are being applied to policymaking through novel strategies such as the interfaces and receptor model (Hanney et al. 2003) or the 'linkage and exchange' model proposed by the Canadian Health Services Research Foundation (Lomas 2000). Such strategies are promoting collaborative approaches to organizing health research systems. They have also promoted the use of knowledge brokers between researchers and policymakers. In the end, demonstrating the benefits of research for policymaking and for population health and national well-being will be critical (Hanney and González-Block 2006).

Evidence-based policymaking can be made a reality if research and analysis is carefully introduced along the critical steps of issue identification, policy development, implementation, monitoring, evaluation, and feedback. Evidence can provide the rationale for an initial policy direction; it can set out the nature and extent of the problem, suggest possible solutions, look to the likely impacts in the future, and evidence from piloting and evaluation can provide motivation for adjustments to a policy or the way it is to be implemented (Campbell et al. 2007).

Conclusion

Policymaking for the design, implementation, and management of effective, efficient, and equitable health systems is today more critical than ever to address the developing country health challenges. Health policy is being called not only to address the pressing needs of infectious diseases and malnutrition and the emerging problems of violence, lesions, tobacco, and obesity. New challenges are being addressed, including the fight against poverty and the increasing global threats. The belief that sound health policymaking can contribute to democracy, economic growth, and global security has influenced the availability of greater financial resources for health. However, relaxing this constraint has now brought much greater awareness to needs in key areas such as human resources and health system strengthening and research.

The information now being produced can provide valuable guidance to policymakers, although it also threatens to overpower capacities in poor countries. Not only must policymaking be knowledge-based—it must also be result-oriented. Careful planning and skilled management can achieve good results even where financial resources are limited. The countries that have achieved good health at low cost challenge other countries to adapt and adopt relevant aspects of their policies.

Policymakers must give high priority to strategies that will eliminate the major items of the unfinished agenda that still plague many developing countries. Many lives can be saved and much disability prevented by measures like boosting immunization programmes, ensuring access to adequate supplies of safe water and good sanitation, providing effective treatment for common childhood ailments, and ensuring skilled care during childbirth including emergency obstetric care (Center for Global Development 2007). More daunting tasks include the pandemic of HIV/AIDS and the emerging non-communicable challenges, which may require complex and expensive care. Evidence has shown that progress can be made through the application of social and behavioural interventions, which can act on those risks that are responsible for the increasing burden of disease associated to chronic ailments and injuries in the developing world. In addition, developing nations must invest in health system strengthening so they can better respond to the increasingly complex challenges that will define the global and national agendas in the decades ahead.

Key points

- ◆ Health policymaking in developing countries is intricately related to global health policies and actors.
- ◆ Health financing has been increasing, thanks to policy advocacy, but more resources and improved governance are required to meet the MDGs.
- ◆ Policy tools are available to support decision-making at national and global levels.
- ◆ Equity and efficiency trade-offs should be addressed on the basis of sound research.

Public health policy in developed countries

John Powles

Introduction: scope of public health policy

... wise consumption is a far more difficult art than wise production

John Ruskin, 1862 (Ruskin 1985)

The scope and purpose of public health policy may be seen as implicit in widely used definitions of public health. Winslow's definition, as adapted by the Acheson Report in England, is: 'The science and art of preventing disease, prolonging life and promoting health through organised efforts of society' (Secretary of State for Social Services 1988).

Public health policies might thus be thought of as the policies that guide these 'organized efforts' to protect and improve health. The scope of such policies depends a good deal, however, on what is considered to be entailed by 'organized efforts', and on how centrally 'organized efforts' are understood to be related to efforts that are more decentralized, more informal, less organized, perhaps even 'spontaneous'. The relative importance and legitimacy of centralized versus decentralized uses of knowledge in protecting and enhancing health is a central and controversial underlying theme in discussion of public health policy.

We need first to define our scope by deciding which countries are currently classifiable as 'developed'. Many answers are clearly possible, but for the purposes of this chapter the boundary will be drawn as follows: the 31 high-income members of the Organisation for Economic Cooperation and Development (OECD) plus six member states of the European Union (EU) that are not included in the OECD list (these six are indicated with '(EU)' in the following). European developed countries divide into western and 'post-communist' groups: western—Austria, Belgium, Cyprus (EU), Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Italy, Luxembourg, Malta (EU), Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, United Kingdom; post-communist—Bulgaria (EU), Czech Republic, Estonia, Hungary, Latvia (EU), Lithuania (EU), Poland, Romania (EU), Slovakia, Slovenia. OECD members elsewhere include two countries each in East Asia—Japan and South Korea; North America—Canada and the United States; and Oceania—Australia and New Zealand. In addition there is Israel which will be grouped with Western Europe in this discussion.

Discussion of public health policy can be pursued from either end of an epistemological/disciplinary polarity—or from

somewhere in between. At one pole are sociological and political science analyses of how 'health problems make it onto the political agenda' and studies of the social and political processes by which policies come to be articulated, adopted, and implemented. Such investigations may be pursued without formally connecting policies to actual health trends. Oliver's discussion of 'the politics of public health policy' in the United States (Oliver 2006) illustrates this approach. At the other, 'objectivist' or 'scientific' pole are works concerned above all, to assess the effects of policy on health trends. *Successes and Failures of Health Policy in Europe* by Mackenbach and McKee (2013) illustrates this approach. This chapter will begin from this second viewpoint.

The unit of analysis for policy is typically the nation state. The diversity of health experience in developed countries over recent decades provides extremely rich raw material for exploring connections between political and economic institutions and policies on the one hand and health trends on the other. The experience of individual countries will be noted according to what it might be telling us about the variety of experience among developed countries. The chapter will focus on the relationship of policy to average levels of population health, not on relationships with inequalities in health levels within countries. This is dealt with in Chapter 2.3. The topics considered will be deliberately restricted to those most closely linked to the main theme. Specialized topics receive attention elsewhere in this textbook.

The remainder of the chapter will be organized as follows: the second section surveys trends in survival over the last four decades. The third section explores, through case studies of road traffic injuries, tobacco and circulatory diseases, the apparent sources of success in reducing non-communicable diseases (NCDs) and injuries in adults. The fourth section notes two public health failures—obesity and habitat degradation—and the fifth considers wider determinants of average levels of population health. The sixth concludes with a tentative vindication of pluralism—ideological, methodological, and institutional.

Success and failure among developed countries

For the 37 developed countries, proportional changes between 1970 and 2010 in the probability of dying before the 5th birthday (child mortality) and the probability of 15-year-olds dying before their 60th birthday (adult mortality) are shown in Fig. 3.7.1. The

Fig. 3.7.1 Proportional reductions, between 1970 and 2010, in risks* of dying before the 5th birthday and of dying between 15th and 60th birthdays in 37 developed countries, grouped into 21 western European countries (medium blue), ten central and eastern European countries (light blue) and six countries from north America, Australasia, and Asia (dark blue). They are ranked successively in ascending, descending and ascending order to illustrate the extent of variation within and between the groups of countries. (*The calculated risks would apply if mortality rates for each reference year were sustained indefinitely.) Source: data from *The Lancet*, Volume 380, Issue Wang, H. et al., Age-specific and sex-specific mortality in 187 countries, 1970–2010: a systematic analysis for the Global Burden of Disease Study 2010, pp. 2071–94, Online appendix, Copyright © 2012.

absolute adult mortality risks at the end of this period are given in Fig. 3.7.2.

First, a guide to the layout: countries are placed in three groups—Western European countries (in medium blue and on the left) are sorted from worst, left to best, right; next are the post-communist countries (light blue), sorted from best to worst; the third group includes North America, Australasia, and east Asia (dark blue), sorted from worst to best.

This figure reveals broad similarities and stark contrasts. Reductions in child mortality (bottom panel) have been universal and substantial, reaching a remarkable 96 per cent in Portugal (from a 7.4 per cent risk of death before the 5th birthday in 1970 down to a 0.3 per cent risk in 2010). The median reduction in the post-communist countries (76 per cent) was below that for countries of Western Europe (83 per cent), but also slightly better than that for the United States (74 per cent).

As attention moves from changes in the risks of death in childhood to changes in the risks of premature adult death in women and men, the variation within and between country groups increases markedly. Within the Western European group, reductions in the risks of premature adult death were around twice as great for men in Italy, Malta, and Iceland as for men in Greece and Denmark. Far more striking were the disparate performances among the post-communist states—ranging from a halving of risks in Slovenian men to an almost 30 per cent increase in Bulgarian men. (The values for Slovenia for 1970 have been imputed and are more uncertain; however, the documented Slovenian trend was strongly downward through the 1980s, differing from the other countries then under communist rule.) For six of the ten post-communist countries, risks of premature death in men were higher in 2010 than they had been 40 years earlier. The biggest reductions in adult male mortality over this period were in South Korea (71 per cent), followed by Australia (63 per cent). The reduction in the United States (43 per cent) was below the median for Western Europe (50 per cent).

For women outside of post-communist Europe, proportional reductions were broadly comparable to those for men but the rank ordering of countries differed somewhat. Within the post-communist group, heterogeneity was again marked, with Slovenia equalling the best performing Western countries while Latvia and Lithuania failed, in 2010, to regain the level of adult female survival they had achieved 40 years earlier.

The absolute risks of premature adult mortality attained by 2010 (Fig. 3.7.2) also reveal a marked heterogeneity. For males, levels were more than three times higher in Hungary and Estonia (both now classified by the World Bank as high income (World Bank 2013)) than they were in the most favoured countries such as Australia, Switzerland, Netherlands, Malta, Sweden, and Iceland. For females, the range was somewhat less but still exceeded twofold. The poor ranking of US women was notable, with their mortality risks exceeded only by some (but not all) of the post-communist countries.

These data present powerful challenges for those wishing to link attained levels of health to differences in political and economic histories and health policies. The contrast between the relative homogeneity in the reduction in child mortality and the diversity of trends in adults calls for explanation. On the provisional assumption that knowledge-based processes are of primary

Fig. 3.7.2 Risks of dying between the 15th and 60th birthdays based on the age-specific mortality risks of 2010. Countries are ranked separately by sex.

Source: data from *The Lancet*, Volume 380, Issue Wang, H. et al., Age-specific and sex-specific mortality in 187 countries, 1970–2010: a systematic analysis for the Global Burden of Disease Study 2010, pp. 2071–94, Online appendix, Copyright © 2012.

importance in the explanation of health trends, this relative homogeneity could be consistent with:

1. Advances in knowledge of how to protect and enhance child health being widely diffused among professional medical staff and general publics in all developed countries.
2. Action to protect child health, based on that knowledge, being seen as both desirable and legitimate across diverse political settings.
3. Much of this action being amenable to central (state) initiation, coordination or support, resulting in widespread realization of the gains promised by the advances of knowledge (immunization providing an obvious example).

For adults, one question compels attention before all others: why was communist rule in Europe so destructive of adult health in most—but not all—countries? Why was this more so for males than females? And why was this public health failure so specific? It did not, as already noted, apply to child health. Nor was it manifest in adults before around 1970. The public health system developed in the Soviet Union in the 1920s (based on a network of ‘sanitary-epidemiological stations’ and often referred to as the Shemashko system after the first People’s Commissar of Public Health), dealt effectively with the problems, predominantly of communicable disease, that it was designed to address (Field 1967; Riley 2008). The countries of central Europe that implemented this system in the first two decades of communist rule achieved rapid declines in adult mortality: Poland almost closed its life expectancy gap with West Germany by the mid 1960s (Zatonski

1996), and in East Germany adult male mortality was lower than in West Germany until the late 1970s (Fig. 3.7.3) (Anonymous 2013c).

Discussion of the even more extreme trends in Russia has directed attention to the role of alcohol, especially where a high average volume of consumption has been combined with the binge drinking pattern. However, among the developed countries in our sample, the binge drinking pattern is mainly limited to the Baltic states and Poland; it is not typical of countries such as Hungary and Bulgaria, whose poor public health performance also needs explanation.

The Global Burden of Disease 2010 study (henceforth GBD) provides summary estimates of disease burdens in ‘central Europe’ in 1990 and 2010 (this GBD category includes some Balkan countries not included in our ‘post-communist’ group) (Anonymous 2013a). These show that cardiovascular diseases were the dominant contributors to the continuing gap with Western Europe. In 2010, rates of years of life lost from cardiovascular causes were more than twice as high in central as in Western Europe, accounting for 43 per cent of total years of life lost in central Europe, compared to 29 per cent in Western Europe. Estimates from the GBD 2010 study of the contributions of leading risk factors to rates of years of life lost in 1990 and 2010 show substantial contributions from the following risk factors (and risk factor clusters) to the central/west Europe gap in years of life lost in males in both 1990 and 2010:

1. Physiological risk factors (blood pressure, blood cholesterol levels, raised BMI, raised plasma glucose)
2. Diet and physical activity (including intakes of fruit and vegetables, sodium, dietary fats)

Fig. 3.7.3 East and West Germany (former boundaries): trends in the risk of dying between the 15th and 60th birthdays, 1956 to 2010*. (* The calculated risks would apply if mortality rates for each calendar year were sustained indefinitely.) Source: data from *Human Mortality Database*, University of California, Berkeley, USA, and Max Planck Institute for Demographic Research, Germany, available at <http://www.mortality.org>.

3. Tobacco

4. Alcohol.

The gap in the contributions of these risk factors did not generally reduce over this period (which corresponds to the period since the end of communist rule). For females, tobacco and alcohol made smaller contributions to the central/west differences than did the physiological risk factors and diet. The lack of convergence of the burdens attributable to these risk factors between 1990 and 2010 may appear surprising given that the mortality trajectories of most of the post-communist countries changed abruptly in the early years of the post-communist period (Wang et al. 2012). However, the declines in adult mortality risks tended to be of comparable magnitude, proportionally, in the central and the western groups (30–40 per cent over the 20-year period) so while there was consistency in the direction of change, there was little overall convergence in absolute levels by 2010.

The GBD 2010 data also cover the other developed regions. Years of life lost attributable to these leading risk factors tended to be lower in ‘high-income East Asia’ (mainly Japan and South Korea) in both time periods. Trends for Australasia were more favourable than those for North America, consistent with their divergent mortality trends. However, the GBD comparative risk assessments generally fail to illuminate the reasons for the increasing divergence in mortality risks between North America and Western Europe. (Some cautions are in order in interpreting these GBD estimates: sources for risk factor levels were scarce for many countries and gaps were filled using Bayesian imputation (with typical 95 per cent uncertainty ranges of the order of plus or minus 6 per cent). Also aggregation of specific risk factors (especially in the physiological and diet groups) involves some double counting, e.g. the effects of adiposity are partially mediated by effects on blood pressure—so the true combined effects of these aggregates will be smaller than their sums (Lim et al. 2012).)

The poor performance of the United States in terms of population health measures deserves note. This has occurred in spite of

an extraordinarily high level of expenditure on professional medicine and of major investment in the creation of new knowledge in medicine and public health. Comparisons with Australia and with Western Europe for the period since 1970 show that the US disadvantage has extended across a wide range of causes. Trends over time show adult mortality decline slowing in the United States since the 1980s, resulting in increasing the gap with other developed countries; mortality levels reached in the United States by 2010 were comparable to those achieved more than 20 years earlier in the leading countries.

In summary:

1. The sample of 37 countries classified as developed on the basis of recent characteristics has diverse cultural, political, and economic histories.
2. Since 1970 there has been substantial and relatively uniform success in reducing mortality risks in children which contrasts with dramatically unequal achievements in reducing adult mortality risks, especially in men. From around 1970 most central European countries experienced serious institutional failures in responding to these adult mortality risks. Although adult male mortality has declined substantially since the end of communism, in six of the ten post-communist countries the gains in this period have been insufficient to offset the losses of the preceding 20 years.
3. The performance of the United States in reducing adult mortality risks has lagged increasingly behind that of the most successful countries. This lag now exceeds 20 years.
4. Differences in adult mortality risks are mainly due to differences in NCDs, especially cardiovascular diseases, and to injuries. These, in turn, are related to differences in a broad range of NCD and injury risk factors—physiological risk factors, dietary composition, tobacco and alcohol use, and risks associated with motor vehicle use.

These major variations in achieving reductions in adult mortality risks remain poorly explained. The next section considers advances in reducing road traffic injuries, tobacco-related disease, and cardiovascular diseases in the hope of throwing light on the institutional origins of success in reducing risks of these kinds.

Case studies of public health success

Road traffic injuries

Deaths from traffic injury per unit of exposure (e.g. per 10,000 vehicles per year) have fallen around tenfold in many developed countries over the past half century. Despite this outstanding public health success, traffic injuries still ranked 8th in their contribution to the burden of disease and injury in developed countries in 2010 (Anonymous 2013a). Because of the short time lags between control measures and their effects, traffic injury control provides a sensitive field in which to explore the relationship between policy adoption, programme implementation, and health effects.

First, it is appropriate to note that success has not flowed exclusively from centrally initiated policies, especially in the early decades of motorization. Smeed writing in the early 1970s showed that deaths from traffic crashes in relation to the number of registered vehicles had followed a general, and pronounced, downward trend as the number of motor vehicles increased in relation

to population (Smeed's law: deaths/vehicle = 0.0003 (vehicles/population)^{-0.66}) (Smeed 1972). In the mid 1960s, two-thirds of 70 populations analysed by Smeed had rates within 40 per cent of his prediction. This implies that, up until then, societies had generally learnt how to use motor vehicles more safely as familiarity with them and the resources available for safety measures both increased. Because the overall tendency was general, it is unlikely to have depended on the specifics of policies variably adopted. However, over the last four or five decades organized policy responses have clearly made a bigger contribution. The Australian state of Victoria has been a pioneer in traffic injury control and its experience will be briefly reviewed here.

Consistent with Smeed's prediction, deaths per 10,000 vehicle years fell in Victoria as the number of vehicles increased in relation to population—from over 20 in the 1930s to about 9 in the early 1960s. During these early decades, Victoria generally had rates in excess of Smeed's prediction and from the late 1940s onwards, the 'road toll' was increasingly seen to be unacceptable. Early policy responses relied on exhortation—for example, encouraging motorists to sign a pledge to abstain from 'careless and discourteous behaviour' on the roads. This approach was not successful. A campaigning young police surgeon engaged journalists in the cause by taking them to the scenes of alcohol-related accidents on Friday and Saturday nights. A committee of the Royal Australasian College of Surgeons made a case before the parliamentary committee on road safety for more rigorous surveillance and for compulsion. In 1970, these submissions convinced the main political parties to support legislation, the first in the world, compelling Victorians to fit and wear seat belts. Compliance with the new law was high and road deaths fell (Fig. 3.7.4). In 1976, the Victorian parliament was the first in the world to legislate for random breath alcohol testing, responding again to advice from professionals. Deaths declined over the following decade. In 1986, a Transport Accident Commission was established, with secure funding from a levy on motorists. It paid no-fault compensation to those injured, which gave it a financial incentive to reduce injuries. A specified proportion of its spending on injury prevention was

required to be spent on programme evaluation—thus supporting the development of an independent accident research institution. In late 1989, after traffic deaths had begun to rise again, it launched one of the most intensive mass media campaigns ever run in Australia—combined with intensified police enforcement (Davison and Yelland 2004). This combination of intensive mass communication, enforcement and evaluative research has continued. For example, in 2009 police performed 1.24 million random breath tests in a total population of 5.4 million persons (Transport Accident Commission 2013a). A local historian commented in 2004:

Probably nowhere else in the world was the conduct of the individual motorist more closely monitored or more rigorously controlled. Yet, with only occasional grumblings, motorists overwhelmingly accepted these measures. (Davison and Yelland 2004, p. 167)

These strategies of education and enforcement were combined with those of engineering. In 1965, Ralph Nader denounced US cars as 'unsafe at any speed' (Nader 1965). In Australia, the national government negotiated against the resistance of the international automobile industry for 'design rules' to make cars safer—e.g. collapsible steering columns, shatter-proof windshield glass, and the removal of dangerous protrusions from the passenger cabin (T. Ryan, personal communication). For the United States, Robertson has documented the continuing resistance of the motor industry to manufacturing safer cars (Robertson 2010).

By 2010, across developed countries as a whole, transport fatality rates varied more than fivefold from less than 0.6 per 10,000 vehicle years in Switzerland, Sweden, Finland, Malta, and Iceland to more than 3.0 in Latvia, South Korea, and Romania (calculated from data in Anonymous (2013b)). Interestingly, Slovenia (1.06) and the Czech Republic (1.10) outperformed other post-communist states as well as the United States (1.37).

Globally, the success of traffic injury control has depended on institutional evolution over several decades. Pioneer jurisdictions moved from considering traffic injury as a moral issue to a public health one and acted on the advice of professionals—whose knowledge at that time typically reflected its early stage of development.

Fig. 3.7.4 Decline in traffic fatalities per 10,000 vehicles per year, 1960–2010, State of Victoria, Australia and Great Britain.

Source: data from Victoria Transport Accident Commission, Road safety statistical summary (yearly), Transport Accident Commission, Victoria, Australia, Copyright © 2013; and World Health Organization, *Global Status Report on Road Safety 2013: Supporting A Decade of Action*, World Health Organization, Geneva, Switzerland, Copyright © 2013.

Emergent control measures have been multifaceted, extending from modifying driver behaviour (including drink driving and speeding) to the redesign of cars and roads. Sustained reduction of injury rates has depended on the concurrent discovery of what to do — by programme supported research bodies such as the Monash University Accident Research Centre (in Victoria), the Insurance Institute for Highway Safety (in the United States), and the Transport Research Laboratory (in the United Kingdom). A body of experience now exists to guide the intensification of control measures. The United Nations has declared 2011 to 2020 as a Decade of Action for Road Safety resting on five pillars: (1) road safety management, (2) safer roads and mobility, (3) safer vehicles, (4) safer road users, and (5) improved post-crash responses. Illustrating the potential for rapid gains from the application of knowledge built up over previous decades, Spain managed to halve fatality rates in just 5 years (from 1.61 per 10,000 vehicle years in 2005 to 0.80 in 2010 (Dirección General de Tráfico, Spain 2013)).

In addition to the measures considered here for reducing injury risks per unit exposure to car usage, there are other powerful health and environmental considerations favouring a reduction in car use itself and a switch to more active forms of commuting (Woodcock et al. 2009).

Tobacco

The first English-language demonstrations of the quantitative relationships between smoking and lung cancer risk were reported in 1950. By 2010, all of the 37 developed countries except the United States and Switzerland had ratified an international treaty on tobacco control, committing themselves to a full repertoire of evidence-based measures to reduce tobacco smoking (World Health Organization 2013). Over a 60-year interval, the currently established set of measures for tobacco control was invented, tried, and tested—ultimately gaining political support at the highest level.

The early 1950s to the 1970s was a period of gradual clarification at a scientific, professional, political, and public level of the nature and meaning of the health risks arising from tobacco use. The epistemology of professional medicine was still prequantitative. As reports from epidemiological studies accumulated, high-level policy debates continued to revolve around a largely illusory search for ‘proof of causation’ (Pollock 1999). Many physicians remained unconvinced of the hazards. In the United States a 1960 poll found that only one-third of physicians were convinced that smoking was a ‘major cause’ of lung cancer and 43 per cent were still regular smokers (Proctor 2011). Physicians who appreciated the magnitude of the risks and who were in a position to do something about it struggled to find a way forward.

In the late 1950s, George Godber was Deputy Chief Medical Officer in Britain and was very keen to help reduce harm from cigarette smoking. But his superior, the Chief Medical Officer, did not want to take the matter forward with the Minister of Health who was known to be unenthusiastic about taking on the Chancellor of the Exchequer (Treasurer). The Treasury was keen to protect the 15 or so per cent of central government revenue provided by tobacco tax (Berridge 2007). Godber visited Charles Fletcher, a respiratory physician, at a London teaching hospital and invited him to his club for lunch so that they could discuss strategies. They decided on working through the Royal College of Physicians in order to by-pass the Chief Medical Officer. The College took up

the matter energetically and decided to produce a report aimed at a large audience. In 1962, *Smoking and Health* appeared and quickly sold out (Pollock 1999; Lock et al. 1998). The United States followed suit and in 1964 the Surgeon General’s report on *The Health Effects of Smoking* appeared. The mass media covered these reports extensively and Pierce and colleagues have shown that smoking cessation rates in US middle-aged adults were, in turn, responsive to the extent of news coverage (Pierce and Gilpin 2001). Coverage of the Surgeon-General’s report was not the beginning of mass media coverage of smoking and health in the United States—as early as 1946 a news magazine story ‘Cigarettes cause cancer?’, based on experimental work on the carcinogenicity of cigarette tar, was ‘widely read’ (Proctor 2011)—but there is good reason to see it as a turning point in increasing public awareness of the hazards of smoking.

A major difficulty, in the 1950s, was that public health authorities were reluctant to tell adult men how they should behave. Reluctance of this kind had not previously inhibited anti-spitting campaigns to reduce risks of transmitting a communicable disease (tuberculosis). Nor had it inhibited strong and detailed directions to mothers, early in the twentieth century on how they should care for their children (Lewis 1980). But advising adult men to abandon a widely accepted habit was seen as different. Crossing this frontier would ultimately change ‘the discourse of public health’ in Britain and legitimize government activity to promote health favouring lifestyles (Berridge 2007).

Early tobacco control activists set out to build political constituencies in support of action by parliament. This turned out to be a slow process. In the United Kingdom, Kenneth Robinson who was health minister through the mid-1960s said that lack of public support had prevented him acting (Berridge 2007, p. 102). In 1971, the Royal College of Physicians established a pressure group—Action on Smoking and Health—to ‘make non-smoking the norm in society and to inform and educate the public about the death and disease caused by smoking’ (Action on Smoking and Health 2013). Most of the early office holders were activist physicians. Major breakthroughs in mobilizing public support came in the mid to late 1980s in Victoria, Australia and in California. The 1987 Victorian Tobacco Act was the first to secure a hypothecated tax to be allocated to health promotion—in this case to the Victorian Health Promotion Foundation (Vichealth). Vichealth then used this money (AU \$23 million per year—about US \$7 per person per year) to buy out tobacco sponsorship of sporting and arts events and to fund health promotion programmes. The close passage of this Act was the outcome of careful planning, initially conducted in strict secrecy in order to catch the tobacco industry off-guard and prevent it deploying its enormous resources against the Act. Once the campaign was public, the large contributor base of the Anti-Cancer Council of Victoria was mobilized. Newspaper coverage was sympathetic—the main morning paper reported more correspondence on the topic than any other in the paper’s history (Borland et al. 2009). Over 150 000 letters of support were sent to state politicians and church leaders were engaged in the campaign. The idea of an hypothecated tax was taken to California and included in Proposition 99 which won voter approval in November 1988—a victory gained by a largely volunteer workforce of canvassers against massive industry spending (Glanz and Balbach 2000). Twenty per cent of the 25 cents per pack hypothecated tax was to be allocated to education and prevention. Secure

funding enabled the California Tobacco Program to achieve bigger reductions in tobacco consumption than happened elsewhere in the United States (Pierce et al. 2011).

From the 1990s onwards, the tobacco industry has suffered further losses of legitimacy and support in the developed world. In the United States, the 1998 Tobacco Master Settlement Agreement between 46 states and the largest cigarette manufacturers resulted in the industry agreeing to restrict some marketing practices, to dissolve its three main front organizations and to pay the states US \$206 billion (sic) over 25 years to compensate for the extra state medical expenditures attributable to cigarette smoking. Interpretation of the potential effects on the Settlement on tobacco control have been mixed (Schroeder 2004) but the public release of previously secret industry documents disclosed during the discovery phase of the litigation has led to further damage to the industry. Proctor used these documents to show how the industry deliberately and secretly modified the composition of cigarettes to make the smoke more inhalable and the smoker more dependent (Proctor 2011).

In 2006, Philip Morris was convicted by a US federal court under legislation designed to counter organized crime (the Racketeer Influenced and Corrupt Organizations Act) for having: falsely denied that they market to youth, falsely denied that they manipulated cigarette design, falsely represented that light and low-tar cigarettes deliver less nicotine and tar, falsely denied that ETS (second-hand smoke) causes disease and suppressed documents, information, and research (Proctor 2011). In November 2012 they were ordered to make public statements admitting that they had lied to the public (Associated Press 2012). Elsewhere, the closing off of marketing opportunities in high-income countries was taken one step further when, in December 2012, Australia enacted a law requiring that all cigarettes be sold in plain standardized packaging.

In 2008, the World Health Organization (WHO) summarized current 'best practice' in anti-tobacco policy under the abbreviation MPOWER:

Monitor tobacco use and prevention policies

Protect people from tobacco use

Offer help to quit tobacco use

Warn about the dangers of tobacco

Enforce bans on tobacco advertising, promotion and sponsorship

Raise taxes on tobacco. (WHO 2008)

Detailed country profiles are available on the WHO website tracking implementation within this framework (Anonymous 2013e). The most robust indicator of success in reducing cumulative tobacco exposure is lung cancer mortality—preferably at younger ages so as to reflect the recent experience of young adults (Fig. 3.7.5). For males, lung cancer mortality under the age of 50 peaked in nearly all developed countries before the year 2000, implying a peaking of smoking uptake in adolescents before about 1980. The epidemic in females has lagged relative to that in males, with six of the 37 countries (Portugal, Spain, Italy, Greece, Ireland, and Germany) showing rates still rising between 2005 and 2010.

Despite these shifts towards declining deaths from smoking, tobacco was still ranked third, after dietary composition and high blood pressure, as a cause of health loss in developed countries in 2010 (Anonymous 2013a). The century-long epidemics of cigarette smoking and its consequent disease burdens illustrate well

Fig. 3.7.5 Years of life lost from lung cancer deaths in males aged 15–49, rates per 100,000 person years for 1990 and 2010, countries ranked by level in 2010*. (*Years of life lost have been calculated by the Global Burden of Disease Project using a model life table with a life expectancy at birth of 86 years.)

Source: data from *Global Burden of Disease Visualizations*, Institute for Health Metrics and Evaluation, University of Washington, Seattle, USA, Copyright © 2013, available from <http://www.healthmetricsandevaluation.org/gbd/visualizations/country>.

the long time frame over which chronic disease determinants may rise and fall, making campaigns to reduce them into long wars of attrition. Tobacco control also illustrates how the development of quantitative methods has supported appropriate policy responses. With increased acceptance of epidemiological reasoning and its transmission to political and wider publics (for example, Peto et al. 2013), quantitative assessments have become more central to policy deliberations, facilitating effective institutional responses, nationally and globally.

Circulatory diseases

Despite the marked reductions of the last two decades, circulatory diseases, mainly ischaemic heart disease and stroke, remain the leading causes of lost life years in developed countries. The overall change from 1990 to 2010 in the level of lost life years from these diseases is shown in Fig. 3.7.6. There is a clear bi-modality of the mortality levels in 1990 (once Slovenia is transferred out of the post-communist group). On average, mortality halved over this interval. Levels became more similar among the 'other' group of countries; for example, reductions were less in France and Japan which began with the lowest levels in 1990. Among the

Fig. 3.7.6 Distribution of 37 developed countries by rates of life years lost to circulatory diseases in 1990 and 2010.

Source: data from *Global Burden of Disease Visualizations*, Institute for Health Metrics and Evaluation, University of Washington, Seattle, USA, Copyright © 2013, available from <http://www.healthmetricsandevaluation.org/gbd/visualizations/country>.

post-communist group, however, levels became less similar—a reduction of 52 per cent in the Czech Republic contrasted with a reduction of just 15 per cent in Bulgaria. Overall there was no ‘catch-up’ by the post-communist group. The United States performed poorly with a reduction of 39 per cent, compared, for example, to a 53 per cent reduction in the United Kingdom.

These trends prompt three policy-related questions:

1. What have been the main contributors to progress over recent decades?
2. Why have the trends since 1990 in the post-communist group been so diverse?
3. Why has the United States been less successful?

Changes contributing to the decline in circulatory diseases

As with road traffic injuries and tobacco-caused disease, endeavours to control circulatory diseases have been pursued in conjunction with determined attempts to better understand their causes. In the United States, President Harry Truman signed the National Heart Act in June 1948. Between 1950 and 2012 the budget of what was to become the National Heart Lung and Blood Institute rose from US \$10 million to US \$3100 million (National Institutes of Health 2012). The deliberate rapid expansion of research into the causes of ischaemic heart disease contributed strongly to the development of modern epidemiology, including the concept of ‘risk factors’. The causation of these diseases has turned out to be complex. In GBD 2010, 11 dietary, five physiological, and three environmental risk factors plus alcohol and tobacco use were modelled as influencing vascular risk.

Notwithstanding this increasing complexity of the acknowledged determinants of vascular risk, much of its variation, at individual and population levels, continues to be explicable by the three classic risk factors—blood pressure, blood cholesterol concentration, and cigarette smoking—whose quantitative relationship to risk is now well understood. Trends in smoking have already been discussed, including the peaking of the smoking epidemic in young adult males before 1980 in most of the developed countries. Less data is available on trends in blood pressure and blood cholesterol concentrations. Where documented, trends in both sexes in developed countries have tended to follow a broadly similar time course to those of cigarette smoking in males—that is, to have been generally favourable, especially since around 1990 (Danaei et al. 2011; Farzadfar et al. 2011). The development of drugs that are effective in lowering blood pressure and blood cholesterol concentrations has enabled clinicians to also make an important contribution to the prevention of these diseases. More effective treatments for heart attacks and for precursor coronary artery disease also mean that the trends in mortality from heart attack reflect not only the extent of success in preventing disease onset but also in reducing the risk of death after onset.

In seeking to characterize societal responses to heart disease and stroke one might start with a hypothetical chain from the advance of scientific knowledge to increased professional and public knowledge, constituency building by activists, enactment of policy, programme implementation, changes in risk factors, and finally changes in disease incidence. However such sequences cannot be easily documented or established in a convincing way. Early phases of development were often marked by the formation of physician-led voluntary organizations which sought to mobilize public support for research, prevention, and treatment in many countries: the American Heart Association (founded 1924), the National Heart Foundation in Australia (founded 1959), and the British Heart Foundation (founded 1961). The European Heart Network now unites 31 member organizations from 24 European countries. In Australia, the National Heart Foundation, with extensive public support, was rich enough to actually lead in establishing national risk factor surveys during the 1980s. In Finland, the local government of North Karelia, a district with extremely high risks of premature death from vascular disease, petitioned the national government for support in reducing their disease burden. From this emerged the North Karelia project which spanned epidemiological investigation and mass mobilization to promote dietary change. Finland became an exemplar in the implementation of science-based policies to reduce vascular risk (Puska 2005).

Few countries have long time-series of surveillance data for levels of public knowledge of risk factors or of risk factor levels. For the United States, data from the National Health and Nutrition Examination Survey is available from the early 1960s. These show substantial reductions in the prevalence of hypertension—from 31 per cent in 1960–1962 to 17 per cent in 1999–2000 (Gregg et al. 2005) with no further reduction to 2007–2008 (Yoon et al. 2010). The prevalence of raised blood cholesterol fell from 34 per cent in the early 1960s to 17 per cent at the end of the 1990s (Gregg et al. 2005), with little further improvement since (CDC 2011).

Capewell and colleagues have shown, in a series of studies, that favourable shifts in risk factors contributed much more than clinical measures (pharmacoprevention plus treatment) to

the reductions in years of life lost from ischaemic heart disease in Scotland (1975–1994), United States (1980–2000), Ireland (1985–2000), and England and Wales (1981–2000) (Gouda et al. 2012).

To all of these activities intended to reduce disease risk must be added other background factors. As early as the 1960s, results from the study of ‘Coronary Heart Disease in Seven Countries’ confirmed that local food cultures varied markedly in their effects on coronary risk—protective in the Mediterranean area and in Japan and adverse, for example, in northern Europe (Keys 1980). Favourable trajectories in mortality from circulatory diseases in countries such as France and Japan may owe as much to protective material cultures as to deliberate efforts to reduce risk. While the effects of rising incomes on animal fat and cigarette consumption may have been adverse in the early decades of the twentieth century, once the associated risks were understood, rising incomes will have brought benefits, for example, via the ability to support further scientific research and by the diversification of food supplies—reduced fat dairy products, margarines with low trans-fat content, year-round supplies of fresh fruit and vegetables, etc. Richer populations can also afford the relatively expensive strategy of controlling blood pressure and high cholesterol by long-term medication. These changing patterns of association between vascular risk factors and national income levels have recently been described (Danaei et al. 2013).

The diverse trends of the post-communist countries

The constellation of institutional responses and background trends just noted was associated with marked declines in vascular diseases in Western countries that were not matched by comparable declines in the European communist countries. In the case of males, the gap was widened by actual increases in incidence in the communist world. But even in the case of females, declines in the West were not matched by declines in the East: for example, rates of vascular mortality in middle-aged women were 1.5 times higher in Hungary than in Spain in the 1950s but a remarkable 4.5 times higher in the 1990s. All of the increase in the difference was due to favourable changes in Spain that failed to occur in Hungary (author’s analyses using data from Anonymous (2013f)).

The communist countries failed to build the scientific foundations for responding to these diseases: they did not invest in the relevant science and they failed to make good use of international findings. The early years of the Soviet regime had been characterized by an enthusiasm for science but subsequent developments were not favourable to population-based aetiological research in medicine. The policy of Nikolai Semashko, first People’s Commissar of Public Health, of integrating prevention and treatment led, in practice, to the domination of Soviet medicine by clinicians rather than by public health experts (Terris 1988); legacies of the ‘Lysenko affair’ weakened all biological sciences (Krementsov 1997), the control of science through hierarchical systems of research institutes limited innovation, while Soviet political economy saw the route to human betterment through the physical domination of nature, not by attending to the biological bases of human well-being—hence the physical sciences and engineering were valued and rewarded more than medicine (Field 1967). These adverse internal characteristics were augmented by the isolation of the cold war years; as late as 1988, Terris

observed that there were no Soviet members of the International Epidemiological Association (Terris 1988). The transformative potential of the quantitative revolution in medicine and, in particular, of the randomized trial, was never realized. Finally, empty shelves in the shops and continuing consumer frustration may not have provided a propitious background for programmes promoting dietary prudence.

Despite these difficulties, the Soviet model of medicine and public health, as broadly adopted in the European communist states, had been initially successful—until it met its nemesis: NCDs of adults. With these it failed, spectacularly and tragically. Twenty years after the fall of communism, nearly all of the post-communist states in our sample continue on less favourable adult survival trajectories than their Western counterparts. Exceptions are Slovenia and the Czech Republic, whose female populations had overtaken the United States by 2010, and East German women, who caught up to their Western counterparts, within the ambience of a reunified Germany, around the year 2000 (Fig. 3.7.3).

Mackenbach, McKee, and colleagues have made a detailed empirical analysis of the correlates of ‘health policy performance’ among 42 European countries during the first decade of the new millennium. (Their sample differs from the one for this chapter in including more middle-income countries from the former USSR and the Balkans and in not including North America, Australasia, Japan, and South Korea.) Their composite ‘health policy performance score’ combined information on a maximum of 27 indicators across ten policy areas. They explored the association of this score with income per person, score on the survival/self-realization scale from the World Values Survey, ‘democracy’, government effectiveness, political orientation (proportion of cabinet seats held by left-wing parties between 1990 and 2009), and ethnic fractionalization. They did not include an indicator of economic inequality. Political composition of governments was not associated with the outcome. In a multivariate analysis only the survival/self-expression score ($r^2 = 87$ per cent) and ethnic fractionalization (combined $r^2 = 90$ per cent) were significant. They conclude:

These findings indicate that performance on health policy is driven substantially by the dominant values in the population, for example because a popular demand to do something is communicated to politicians. (Mackenbach and McKee 2013, p. 338)

Higher average scores on the self-expression scale correspond to greater satisfaction with levels of personal autonomy and with levels of creativity at work. However it is interpreted, average scores on this scale clearly separate the three higher-income members of the post-communist group with divergent health outcomes—Slovenia and the Czech Republic each had mean scores of 0.38 on the self-expression scale in the 2006 wave of the World Values Survey and also the most favourable survival trends in contrast to Hungary with a score of –1.22 and less favourable survival trends.

For three of the main mortality indicators for 2010 used in this chapter—traffic deaths per 10,000 vehicle years, years of life lost from male lung cancer deaths before age 50, and years of life lost from circulatory diseases—the ratio of the median level in the post-communist group to the median of west European group exceeds 2.5. This suggests a persisting lag in developing cultures of prudent consumption across motor cars, tobacco, and diet. Countries in the post-communist group tend to show consistent rankings across these and related variables.

Why has the United States been less successful?

The experience of the United States may be compared with the medians for the 26 other developed countries excluding the post-communist group. Such comparisons show the United States to have a mean income 30 per cent above the reference and a strong orientation towards self-expression in the World Values Survey (mean score 1.76, reference 1.13) (James et al. 2012; Anonymous 2013d). To these advantages must be added the relative strength of knowledge infrastructures in medicine and public health and the remarkably high levels of expenditure on professional medicine. Despite these multiple advantages, mortality risks between the ages of 15 and 60 are around 50 per cent higher in each sex than in the reference and the United States has been falling further behind over time. These observations suggest that opportunities for health improvement in the United States are being restricted by other societal characteristics.

These developments have not passed unnoticed in the United States, with a major report (*Shorter Lives, Poorer Health*) from the National Research Council and the Institute of Medicine in 2013 (Woolf and Aron 2013a). The authors show that factors influencing the distribution of health levels, while important in themselves and the subject of much attention in the literature, are not at the heart of the problem: privileged groups in the United States are similarly disadvantaged relative to their counterparts in other countries. The US disadvantage extends across a range of major health outcomes. Traffic fatalities per 10,000 vehicle years are 65 per cent higher than the developed country reference; years of life lost from lung cancer under age 50 is 9 per cent higher for males but 65 per cent higher for females and years of life lost from circulatory diseases are 34 per cent higher. As with the post-communist group of countries, patterns of commodity use unfavourable to health appear to underlie the US disadvantage. In order 'to make sense of why Americans are more likely to engage in certain unhealthy behaviors or injurious practices...', the role of societal values in enacting or resisting countermeasures cannot be ignored' (Woolf and Aron 2013a, p. 222).

The report cites approvingly another National Academies report on traffic injuries which shows how jurisdictions in the United States resist the application of measures proven effective elsewhere for reducing drink driving, increasing seat belt and motorcycle helmet use and controlling speed (Woolf and Aron 2013a, pp. 227–31). The main report concludes that it will be 'important for Americans to engage in a thoughtful discussion about what investments and compromises they are willing to make to keep pace with health advances other countries are achieving' (Woolf and Aron 2013a, p. 6).

Public health failures

Energy intake, energy expenditure, and obesity

In contrast to the preceding areas of success, this is an area of generalized failure. In developed countries there has been an almost universal tendency for obesity prevalences to rise over recent decades, with this tendency accelerating over the past decade or so (Stevens et al. 2012). Prevalences in males and females in the United States and in males in the Czech Republic now exceed 30 per cent, while prevalences in South Korea and Japan are still below 10 per cent. Surprisingly, trends in attributable

disease burdens from GBD 2010 show little increase through the last decade (Anonymous 2013a) suggesting that favourable trends in background risks for circulatory diseases may have been offsetting much of the potential harm from rising obesity—i.e. an increasing obesity multiplier may have been applied to a shrinking background vascular risk level (Powles et al. 2010).

The UK Foresight Report on 'Tackling obesities' sought to understand and respond to the societal determinants of rising obesity prevalence. 'The technological revolution of the twentieth century has left in its wake an 'obesogenic environment' that serves to expose the biological vulnerability of human beings' (Butland et al. 2007, p. 8). Adequate responses will require 'changes in the environment and organizational behaviour, as well as changes in group, family and individual behaviour' (p. 15), that will need to span generations (p. 131). Parallels with the challenges posed by climate change are noted. So far, however, the authors are able to find few international examples of success.

Habitat degradation and public health

In the early phases of industrialization 'point source' pollution damaged health by contaminating local (or regional) air, water, and soil. Over recent decades, the cumulative effects of global industrialization have been found to be disturbing the large-scale natural processes on which the stability of our human habitat and the long-term health and survival of human populations depend (McMichael 2013) (see also Chapter 2.8). Human-induced climate change is part of a larger pattern of systemic environmental and ecological changes due to the now excessive and widespread human pressures on the biosphere (Rockstrom et al. 2009). These include stratospheric ozone depletion, ocean acidification, soil losses and groundwater depletion, disruption of global nitrogen and phosphorus cycles, and rapid loss of biodiversity. The WHO, through its Director General, noted in 2008 that 'climate change endangers health in fundamental ways': disruption of food production, increased storms and floods, water shortage and excess, heatwaves and changes in the distribution of insect vectors of disease (Chan 2008).

Lagged, large-scale adverse effects of these kinds differ qualitatively, and very significantly, from other connections between productive activity and health—their main threats to health lie ahead of us, as current trends continue, they are global or regional in scope, they are mainly predicted rather than currently manifest, and their specific manifestation in a given time and place is highly uncertain—as are the final pathways by which the health of individuals will be harmed. Despite these differences, there are common threads with the epidemics of NCD. Both arise from attending exclusively to human wants rather than also attending to the biological requirements for human well-being. Adequate responses cannot be built on approaches that respond only to demand. The rewards of economic development, so highly valued by economic liberals, can now only be protected by attending to the objective requirements for their sustainability—by means which economic liberals mostly oppose.

Governments and public health professionals in developed countries have responded to the challenge of climate change in three main ways:

1. First, by securing the participation of public health experts in national and global expert panels assessing climate change, notably the 6 yearly Intergovernmental Panel on Climate

Change (IPCC) Assessments, the fifth of which was published in 2013–14. Such participation is especially important for the Health chapter (Working Group II), but is not limited to it.

2. Second, by identifying and elaborating strategies that promise ‘double dividends’—that is, changes that both favour health and mitigate climate change. Examples include transport policies that both increase physical activity and reduce carbon emissions (Woodcock et al. 2009) and reductions in red and processed meat consumption that reduce both risks of NCDs and the major greenhouse gas emissions produced by livestock production (Aston et al. 2012).
3. Third, by ensuring that the medical care sector, itself a major industry in developed countries, acts as an exemplar in moving towards sustainability. For example the English National Health Service has a Sustainable Development Unit ‘to ensure that the health and care system fulfils its potential as a leading sustainable and low carbon service’ (NHS Sustainable Development Unit 2013). The English unit is a founding member of the Global Green and Healthy Hospitals network (Global Green and Healthy Hospitals n.d.).

Wider determinants of the public health

The marked increase over the past two decades or so in discussion of the ‘social’ or ‘wider’ determinants of health has been associated with the belief that distributional considerations are central to understanding these phenomena. The final report of the WHO Commission on the Social Determinants of Health, for example, was titled: *Closing the Gap in a Generation: Health Equity Through Action on the Social Determinants of Health* (Commission on the Social Determinants of Health 2008). Evidence presented in this chapter, consistent with that marshalled by Mackenbach and McKee for Europe (Mackenbach and McKee 2013) and with the US National Academies report (Woolf and Aron 2013a), suggests that it may instead be helpful to distinguish between the wider determinants of average levels of population health and the wider determinants of the dispersion (or inequality) of health levels within populations.

A pragmatic reason for doing so is the availability of evidence on variation in the dependent variable. We have seen that multiple indicators are available, showing variation in average levels across developed countries that are often greater than twofold. Variation in dispersion, as measured, for example, by the relative index of inequality, may in some cases be of comparable magnitude, but tends to be available in comparable form for fewer populations and time periods (Mackenbach et al. 2008). Investigation of the causes of variation in average levels of population health may therefore be more empirically tractable than explanation of variations in levels of inequality within populations.

A second reason for this distinction is that variation in levels of economic or social equality may not be central to the explanation of variation in average levels of health. For example, the communist states of Europe had both more equal distribution of incomes and much less favourable average levels of adult health. The US report discussed earlier also notes that differences in levels of inequality do not account for poorer outcomes in the United States because the US disadvantage is experienced across all social strata.

A third reason is that when considering wider determinants of average levels of health it is possible to give due recognition to the institutional and ideological determinants of the consumption habits underlying variation in health levels. By contrast, much discussion of the wider determinants of health inequalities considers consumption habits to be characteristic of individuals—as in the oxymoron ‘individual lifestyle’. (The concept of a style is intrinsically social (Cockerham et al. 1997).) The much cited Dahlgren/Whitehead model places ‘individual lifestyle factors’ in the zone closest to individuals (Bambra et al. 2010).

I will briefly consider the following as ‘wider determinants’ of average levels of population health (henceforward just public health):

1. Knowledge
2. Income
3. Values
4. Corporate power
5. Political economy.

Knowledge

Avoidable weaknesses in the knowledge infrastructure for public health prevented the European communist countries from responding effectively to the challenge of NCD in adults. Outcomes for these countries in the post-communist period were noted to be variable, with Slovenia and the Czech Republic showing the biggest gains. There is little evidence, however, of these countries making determined efforts in the post-communist period—via research funding, attractive scholarships tenable internationally, etc.—to build scientific capacities supportive of modern responses to NCD. A bibliometric index of research papers published in 2001–2010 and indexed in PubMed with MESH terms relating to the epidemiology and control of heart disease and stroke shows that the median for the post-communist group of countries was only 15 per million mid-period population, compared with five times that rate in the United States and the United Kingdom and more than ten times that rate in Sweden, Denmark, and Israel (personal analyses).

It is likely that relevant national research strengths are much more important in the early developmental phases of responses to public health challenges. Knowledgeable experts were seen to have played important roles in the early development of measures to control traffic injury, to reduce tobacco use and to control cardiovascular risk—even though relevant knowledge was, at those early stages, often tentative and incomplete. As control measures against these challenges have been developed, tested and achieved international acceptance, countries are able to make use of them, to some extent independent of their local research strengths in these areas. In the long run, knowing what to do has been powerfully permissive of it (eventually) being done.

Income

Other things being equal, higher incomes should facilitate health protective patterns of living: for example, safer cars and roads will be more affordable, as will a wider variety of foods associated with lower circulatory disease risk. The median income level among the post-communist group of countries remains 50 per cent below the

reference group and this could be constraining the implementation of public health programmes in those countries. Mackenbach and McKee found that gross domestic product per person (in 2000) was a strong correlate of their 'health policy performance score' across European countries (Mackenbach and McKee 2013). However, discordant national experiences reviewed here indicate that income per se has been unable to over-ride the effects of unfavourable institutional circumstances: between 1970 and 1990, real income per person is estimated to have almost doubled in Hungary and to have more than doubled in Bulgaria but over these intervals the risks of dying between ages 15 and 60 rose from 20 per cent to 30 per cent in Hungarian men and from 16 per cent to 22 per cent in Bulgarian men. In 2010, the United States ranked third out of 37 in real income per person (using purchasing power adjusted estimates (James et al. 2012)) but 30th out of 37 for adult female survival and 27th out of 37 for adult male survival. A high level of command over resources has not automatically led to patterns of resource use favourable to health. Other circumstances need also to be favourable.

Values

As noted earlier, Mackenbach and McKee found that the 'self-realization' score from the World Values Survey was even more strongly associated with 'policy performance' than was income (Mackenbach and McKee 2013, p. 338). It is hypothesized that the attainment of material security enables more attention to be paid to self-realization—including a greater interest in reducing longer term health risks. Part of the limited catch up of the post-communist states could plausibly be associated with the extent of their other preoccupations. However, evidence on this topic is limited. The United States scores highly on 'self-expression'. Its deviance in the World Values Survey is in the strength of 'traditional/religious values'; on this dimension it sits with Latin American and Islamic states.

Corporate power

Large corporations are a salient feature of the contemporary capitalist world. In 2000, of the 100 largest economic entities in the world (ranked by value added), 63 were countries and 37 were corporations (De Grauwe and Camerman 2002). Adverse effects of corporations on health are claimed via three channels: (1) illegal behaviour, (2) disreputable behaviour, and (3) normal behaviour.

As already noted, the cigarette industry illustrates the first: by making cigarette smoke more inhalable and cigarettes more dependence creating and therefore more deadly while conspiring to conceal the fact. Claimed disreputable actions include the behaviour of the 'big food' companies, for example, in marketing directed to children (Brownell and Warner 2009).

The third claim is that corporations, in their legal obligation to give priority to returns to shareholders, will automatically devalue ends that are not monetized and not relevant to their profitability (Wiist 2010). In this view it is inappropriate to regard corporations as good or bad. Corporations in the cigarette, alcohol, motor vehicle, pharmaceutical, and food industries damage health as a consequence of the objectives they are required to pursue. The appropriate response, for public health advocates, is to seek to limit corporate power by 'redesigning or restructuring the corporation as an institution'—for example, by banning all corporate political activity, by removing the right to legal personhood,

and by eliminating or reducing limited liability (Wiist 2010, pp. 47–48). This analysis is largely based on US sources. The volume cited does not explain how the health disadvantage of the United States compared to other developed capitalist countries is attributable to differences in the legal privileges of corporations.

Prevailing ideas on political economy

Theories of political economy lie close to the surface of many discussions of policies to change consumption habits in order to prevent disease. In the United States, liberal/libertarian political economy exerts pervasive influence. Both the neo-classical ('Chicago') and 'Austrian' schools seek to minimize state coercion and emphasize the virtues of markets in regulating economic activity and individual behaviours.

Many public health policies to reduce chronic disease and injury do indeed include coercive elements e.g. traffic law, bans on indoor smoking etc. The liberal criticism of them as coercive is, however, weakened by its abstraction from social and historical contexts. As was noted in the case of measures to reduce traffic injury in Victoria, high levels of surveillance and coercion may achieve wide public support because of the perceived benefits in safer car travel produced. In practice, for public health policies to be enacted in democratic polities, the case for any coercive elements has to be made in the light of the health benefits expected. They cannot be introduced behind the public's back.

A more fundamental liberal/libertarian criticism is that even where public health policies are effective in improving health, this will not constitute an improvement in well-being (utility) if it is achieved by violating existing consumer preferences. This is because, in the liberal/libertarian perspective, value arises solely from meeting the subjective preferences of consumers—by fulfilling their demands, not by meeting their needs. This perspective is consistent with neo-classical economic approaches which Hodgson characterizes as those that:

1. Assume rational, utility-maximizing behaviour by agents with given and stable preferences.
2. Focus on attained equilibrium states or movements towards them.
3. Are marked by an absence of chronic information problems (Hodgson 2013a).

Gary Becker's elaboration of 'rational choice theory' illustrates a neo-classical approach to consumption and its connections to well-being. For Becker, the household is the locus of production of final commodities such as health, social standing, and 'pleasures of the senses', using inputs such as market goods, time, and consumer and social capital (Becker 1996b). As societies become richer, time becomes relatively scarcer and market goods less so. The capacity to gain utility using time and market goods is enhanced by education and 'social' resources (the latter conceived in a restricted sense). Within this framework, Becker is able to interpret opiate, alcohol and nicotine addiction as 'rational' (Becker 1996a). Given this, the case for public policies to reduce them loses legitimacy.

The Austrian school of liberal political economy differs in important respects from the neo-classical school (Aranzadi del Cerro 2006). It is exemplified in works such as Friedrich Hayek's *Constitution of Liberty* (Hayek 1960) (acknowledged by Margaret

Thatcher as a key influence on her programme to revive economic liberalism in 1980s Britain) and Ludwig von Mises' *Human Action* (von Mises and Greaves 2007). Although no less determined to minimize state coercion and to extol the virtues of markets, the Austrian approach provides a richer account of the way in which the decentralized exchange of knowledge through markets creates stable social orders (catallaxis). Gamble sees Hayek's approach as rooted in 'epistemological pessimism', regarding as a 'fatal conceit' 'the belief that in the modern era human beings were able to throw off the chains of tradition, superstition, convention, and precedent and design institutions, choose morals, invent values, and plan societies as though they were starting from a blank sheet' (Gamble 2006). Hayek preferred instead 'the tacit knowledge encoded in the traditions, conventions, and rules which had been inherited, and were the fruit of human action over millennia'. Hayek was inclined to oppose all centralized uses of knowledge—not just by governments seeking to regulate economic life but also by elite groups of scientists seeking disproportionate influence on public affairs (variously referred to as scientism or 'constructivism'). The suspicion among US liberal/libertarian groups of bodies such as the Intergovernmental Panel on Climate Change, to the extent that it is not based on irrational 'denialism' (Diethelm and McKee 2009), likely owes a good deal to this sentiment.

Gamble notes how Hayek's logic could be turned in the opposite direction: the way in which he 'approaches the social world is paralleled in the way in which environmentalists approach the natural world. Both are conceived as extremely delicate, living organisms... whose operations are imperfectly understood'. But Hayek 'never extended to natural science and technology his critique of constructivist rationalism in social science'.

Alternatives to liberal/libertarian political economy are provided by heterodox approaches. In Europe, the best established of these is that of evolutionary political economy (European Association for Evolutionary Political Economy n.d.). These typically depart from the neo-classical approach by:

1. Abandoning exclusive reliance on a subjective theory of value by also valuing the meeting of objective needs.
2. Seeking greater consistency with the substantive findings of the natural sciences.
3. Attending to human capacities for creativity, morality and institutional evolution.

Hodgson's *From Pleasure Machines to Moral Communities: An Evolutionary Economics Without Homo Economicus* (Hodgson 2013) illustrates an approach likely to be more congenial to public health professionals. Hodgson embraces a pluralist theory of value—'health is an objective, universal need, irrespective of whether it is also a want' (Hodgson 2013, p. 174; Woolf and Aron 2013a)—and notes the consequent difficulties in arbitrating needs:

Some middle ground must be found between the propositions that the consumer always knows best and the state or the experts always know best: neither extreme is defensible... The problem is to design institutions that set up a creative dialogue between individual preferences and expert advice, embody mechanisms to scrutinize the skills and claims of experts, and facilitate the creation and distribution of relevant knowledge. (Hodgson 2013, p. 192)

Hodgson does not evade the fact that '[S]cience is unavoidably elitist. It depends on the interactions and evaluations of a selected

group of highly trained experts and specialists' (Hodgson 2013, p. 223). He also considers many forms of collective action to be well founded because our evolution has left us 'biologically and culturally primed to be sensitive to such issues as fairness, care for the needs of others and an unspoiled environment' (p. 204). By contrast it is a fatal weakness of neo-classical welfare economics that it can provide no useful guidance when confronted with the challenge of climate change (p. 197).

Clarifying theoretical viewpoints held in good faith is one thing, but in real political contests, propositions may be advanced for the purpose of defending vested interests in ways that bear little connection to the actual beliefs of those advancing them—as has been documented in the behaviour of the cigarette manufacturers. Especially in the United States, liberal/libertarian anti-state arguments are heavily promoted by those who stand to gain from them (Cohen et al. 2000). But such beliefs also have strong historical and constitutional foundations in that country. Individual autonomy and freedom of choice are valued, rather than fairness and social solidarity, leading to hostility to regulation that is seen to infringe choice, for example, firearms control. Whatever their origins, the strength of 'anti-government' viewpoints makes it difficult for the United States to implement public health policies found effective elsewhere (Woolf and Aron 2013b).

Conclusion

For this chapter, a sample of 37 developed countries was identified based on their recent status as high-income members of the OECD or membership of the EU. They are heterogeneous in culture and in their political and economic histories. When examining changes in survival patterns over the last 40 years, it was found that gains in child survival were substantial and broadly similar across all 37 countries. By contrast, trends in adult survival between ages 15 and 60 differed dramatically. These differences mainly arose from a relatively small group of diseases and injuries related to patterns of commodity consumption. Attention was therefore focused on how differing experience of these conditions might have been related to those differences in political histories and public health policies most likely to influence relevant consumption habits.

Although the wider determinants of inequalities in health is an important topic, for the purpose of this chapter it was found to be more useful to concentrate on wider determinants of average levels of population health. In relation to broad systems of political economy, poorer outcomes were associated with the extremes of the state-centred systems of the European communist countries (and their institutional legacies in the post-communist period) and the United States, where ideas of liberal/libertarian political economy and associated 'anti-government' sentiments are most dominant. Health trends in countries lying between these two poles have not shown any straightforward association with the political alignment of their governments. European countries tend to have a wider range of political opinion represented both inside and outside their parliaments. In many, the influence of non-liberal Catholic social teaching on right-of-centre parties has been important, and has moderated the linkage between right-of-centre politics and economic liberalism. These countries have generally pursued more pragmatic or pluralist approaches to protecting

adult health—consistent with Popper’s idea of ‘piecemeal social engineering’ (Popper 1957). It is thus the capacity of the dominant liberal/libertarian political economy in the United States to restrict more pluralist approaches that appears to have been important. Notwithstanding these obstructions there have been strong state or city level programmes for NCD control within the United States—for example, the California Tobacco Control Programme and the more recent programmes of the New York City Health Department (New York City Health Department 2014). As awareness within the US that it is falling behind other developed countries increases, ways may be found to further develop and replicate public health programmes that are acceptable and effective within the US context.

Some recent trends in developed countries have not been favourable. Without effective responses to the rise in obesity, the substantial health gains of the last couple of decades may erode. The medium- to longer-term future is clouded by potential large-scale harms from climate change. Meeting these challenges will require the renovation and transformation of economic, social and public health institutions—complex processes, that are presenting difficult challenges to public health professionals as to others. The recent run of success may not last.

Key points

- ◆ Over the last four decades, developed countries have achieved broadly similar success in reducing risks of death in childhood but have varied markedly in their success in reducing adult mortality.
- ◆ Most variation in adult mortality risks is accounted for by circulatory diseases and a limited number of other conditions related to patterns of commodity consumption.
- ◆ The European communist countries failed tragically to control adult mortality risks; improvements since the fall of communism have been variable.
- ◆ The United States has also performed poorly, especially in the light of its financial and scientific resources; it now lags more than 20 years behind its comparators.
- ◆ Effective counter-measures for traffic injuries, tobacco-caused disease, and circulatory disease evolved over time; early leadership came mostly from informed professionals, then broadened as supportive constituencies were built, knowledge advanced, and effective measures were identified and given international sanction.
- ◆ The rising prevalence of obesity and habitat degradation by greenhouse gas emissions are current policy failures.
- ◆ Theories of political economy that have little respect for biologically based needs may, where dominant, restrict societal responses to NCD and habitat degradation.
- ◆ Prospects for further sustainable health gains are now uncertain, but are likely to improve under conditions of pluralism.

International efforts to promote public health

Douglas Bettcher,¹ Katherine DeLand, Gemma Lien, Fernando Gonzalez-Martinez, Anne Huvos, Steven Solomon, Ulrike Schwerdtfeger, Haik Nikogosian, Angelika Tritscher, and Julia Dalzell

Introduction: global health governance, international health instruments, and global public goods

As detailed in Chapter 1.5 on globalization, the world today is becoming less recognizable as a system of independent states and is instead increasingly viewed as a complex network of interdependent states and non-state actors, linked in multifaceted ways. Globalization forces such as migration, trade, food production and movement, insect/microbe resistance to drugs, and environmental change increase the speed and geographical scope of cross-border health risks and directly challenge the existing system of international health governance defined by national borders (Dodgson et al. 2002). In light of these shifts in the broad global landscapes, the notion of global health governance (GHG) should also shift and be recast to reflect the new realities. This chapter continues the examination of GHG begun in Chapter 1.5, expanding the discussion to address international legal instruments and global public goods as key elements of GHG.

GHG has been defined as ‘the use of formal and informal institutions, rules and processes by states, intergovernmental organizations, and non-state actors to deal with challenges to health that require cross-border collective action to address effectively’ (Fidler and Calamaras 2010, p. 3). The fundamental idea underpinning GHG is that the world has assets capable of improving population health and these should be deployed and distributed more equitably and effectively (WHO 2013a).

The essential functions of GHG ‘are generally agreed upon and include convening, defining shared values, ensuring coherence, establishing standards and regulatory frameworks, providing direction (e.g. setting priorities), mobilizing and aligning resources, and promoting research’ (Sridhar et al. 2008/2009, p. 2).

International governmental cooperation in the governance of health issues resulted in the establishment of the World Health Organization (WHO) in 1948, arguably one of the greatest achievements of GHG to date. Since then, various forms and mechanisms of health governance have been developed under

the auspices of WHO, in accord with the provisions of the WHO Constitution: formal decision-making forums (for example, the World Health Assembly), legally binding instruments (for example, the International Health Regulations (2005) and the WHO Framework Convention on Tobacco Control (WHO FCTC)), voluntary agreements (such as the Pandemic Influenza Preparedness (PIP) Framework), and shared goals or strategies (such as the health objectives contained in the Millennium Development Goals). As a formalized, intergovernmental agency, WHO has provided and continues to provide a robust platform for state-to-state negotiations on agreed approaches towards global health aims.

However, as globalization has progressed and our understanding of the complexity of global health, health interventions, and health systems has become more sophisticated, it is clear that GHG is no longer solely a matter of intergovernmental concern, nor is there always the necessary political will or mandate to address all transborder public health issues through governmental mechanisms. As noted in Chapter 1.5, often civil society and foundations seek to fill these gaps. More and more commonly, the public health community is also creating public–private partnerships, like the Global Fund to Fight AIDS, Tuberculosis and Malaria (Global Fund), the Global Alliance for Vaccines and Immunization (GAVI Alliance), and Roll Back Malaria. It is worth noting that, while these partnerships involve WHO and other United Nations (UN) agencies, all are outside of the purely intergovernmental context, to allow for adequate flexibility for the formal participation and contribution of key non-state actors.

Global public–private partnerships (GPPPs) represent a qualitatively new hybrid form of governance, bringing together in a partnership bodies such as intergovernmental organizations, states, non-governmental organizations, development banks, philanthropic foundations, and multinational corporations to achieve a shared health-creating goal. The Global Polio Eradication Initiative is one such example of a GPPP, bringing together WHO, the UN Children’s Fund (UNICEF), the United States Centers for Disease Control and Prevention, and Rotary International in the effort to eradicate polio.

Critics of these new approaches are concerned that public and private goals are not mutually compatible and argue that the new initiatives may be susceptible to undue influence of private interests. The increase in the number of GPPPs in the health sector may have ‘significant implications for the exercise of governance of health through the multilateral UN regime’ and may ultimately ‘undermine the ability of WHO to effectively contribute to health governance at the global level’ (Buse and Walt 2002). These new initiatives may increase competition for scarce resources and influence and have the potential to cause verticalization within health policymaking. To be most effective, GHG must include both vertical and horizontal approaches, particularly with regard to complicated issues like those identified in Chapter 1.5 (i.e. tobacco, obesity and infectious disease outbreaks or public health emergencies). The harmonization of efforts by the traditional entities, like WHO, and the new contributors, like the GPPPs, is key to the longer-term success of GHG in addressing major health concerns.

Two distinct concepts have begun to emerge in the field of GHG: *governance of health* and *governance for health*. Governance of health entails coordinating and directing public health efforts (for example, through resolutions of the World Health Assembly). Governance for health, however, is an advocacy and policy function seeking to influence the governance of other sectors (for example, agriculture, trade, and environment) to include and benefit health efforts (WHO 2013a).

Governance for health recognizes that a broad range of social, economic, political, and environmental determinants impact population health and that public health solutions must be found to address issues such as poverty, access to affordable healthcare and medicines, climate change, and food security. States are beginning to recognize that health is important not just for population well-being, but also for national and international security, economic well-being, and the economic and social development of developing countries (Fidler and Calamaras 2010). Approaching these issues from a ‘health-in-all-policies’ perspective enables governments to factor health impact into law and norm development.

However, it is also essential to consider the role of non-state actors. As the global health policy landscape responds to globalization, non-state actors like multinational corporations and philanthropic foundations become more and more involved. While interest in and support for public health are critical, it is worth noting that the substantial financial influence these non-state actors can wield may lead to a shift not only in how global health is funded, but in what is funded (Smith 2010).

It has been argued that the biggest obstacle for GHG ‘might not be unstructured plurality but the plurality of incapacity’, given that despite large donors and the increased profile of GHG, ‘the political and financial responsibility for public health infrastructure and capacity’ still falls on governments (Fidler 2007). More needs to be done to build and sustain public health systems and capabilities within states. Whether hard (i.e. binding) or soft (i.e. non-binding) law is developed through GHG, the fact remains that states still need the national capacity to implement and enforce those laws.

To remedy the ‘unstructured plurality’ of the current fractured global landscape, it has been suggested that a new global agreement or a treaty on global health may be the answer (Kickbusch 2006; Gostin 2007). Other suggestions include adding a ‘Committee C’

to the World Health Assembly with the aim of providing a forum for non-state actors (Silberschmidt et al. 2008). As part of its recently initiated reform process, WHO’s Executive Board and the World Health Assembly have both considered next steps in developing a policy on engagement with non-governmental organizations (WHO 2013a, 2013b). Regardless of the approach taken, WHO’s Constitution mandates it to act as ‘the directing and coordinating authority on international health work’ (WHO 1946).

Global public goods

Economists have used the term *public good* for centuries to think about and analyse national governance. A public good is a good that has two characteristics: (1) it is non-rival in consumption—that is, its consumption by an individual does not impede someone else from consuming it—and (2) it is non-excludable, which means that one cannot prevent someone else from consuming it. One example of a public good is street lighting. As a person walks down a street at night, the light illuminates the sidewalk. Using the light does not impede other people from using that same light as they walk. While often tangible, like the street light, public goods can also be intangibles, like security or education. Since public goods tend to be underprovided in the absence of government intervention, due to the ‘free-rider problem’ (i.e. taking advantage of a public good without providing for its existence or maintenance), it is often the role of governments to provide them.

The interconnectedness of states as a result of globalization naturally leads to an increase in domestic public goods common to the interacting states. Correlatively, the singular nature of some of what were once solely domestic public goods has progressively declined as the creation and maintenance of those public goods became shared enterprises. This has led to the emergence of the concept of the global public good (GPG). Kaul et al. define GPG as a public good having three characteristics (Box 3.8.1).

Based on these criteria, health is arguably a GPG. As a public good, health is a positive sum: one person’s good health does not detract from another’s (characteristic 1). Indeed, better individual health usually has positive effects on entire populations—for example, through reduced disease transmission. As health is not only an end in itself but is also inseparable from social and economic welfare, health is also a key element for economic and social growth. An improvement in individual health can improve

Box 3.8.1 Global public goods

1. Covers more than one group of countries.
2. Its benefits [...] reach [...] a broad spectrum of the global population (which means that access to them must not be limited to certain economic classes, gender, religious groups, or any other discrete community).
3. It meets the needs of present generations without jeopardizing those of future generations (Kaul et al. 1999).

Source: data from Kaul, I. et al., ‘Defining global public goods’, in Kaul, I. et al. (Eds), *Global Public Goods: International Cooperation in the 21st Century*, pp. 2–19, Oxford University Press, New York, USA, Copyright © 1999 by the United Nations Development Programme.

the community-level economy and social fabric (characteristics 2 and 3). Furthermore, although the onus of providing health remains primarily on national governments, globalization means that the determinants of health, as well as the requisite means to deliver health, are increasingly global (characteristic 1) (Jamison et al. 1998).

Two forces are moving health progressively toward the centre of the stage in the discussion of GPGs. First, as already noted, enhanced international linkages in trade, migration and information flows have accelerated the cross-border transmission of disease and the international transfer of non-communicable behavioural health risks. Second, intensified pressure on common-pool global resources, such as air and water, has generated shared, transnational environmental threats. However, the notion of health as a GPG is not uncontested. It has been argued that an individual's health—or even an entire country's health status—primarily benefits only the individual or country and that the resources necessary to provide better health are indeed 'predominantly rival and exclusive' (Woodward and Smith 2003). This school of thought agrees that some aspects of health, including control of globally threatening communicable disease like HIV/AIDS and tuberculosis, may be GPGs, but there is some concern that 'relaxing' the interpretation of GPG to include health may dilute the usefulness of GPGs as means to secure funding (Smith and Woodward 2003). Perhaps most importantly, if health as a GPG is limited to very prescribed circumstances like control of an infectious disease, then it loses its capacity as an organizing principle for global health priorities (Smith et al. 2004).

Nonetheless, even among those who maintain that health is not a GPG, there is a strong sense that collective action and coordination, as the core notion of GPGs, can be used to great and measurable effect to promote and improve global health, through, for instance, the development of international public health legal instruments.

As well as being the means to a GPG end (in this case, health), international instruments *themselves* could also be considered within the rubric of GPGs, insofar as they provide a shared platform for the process of improving social and economic welfare. However, the agreement to coordinate and to act in concert, while critical for reaching a GPG, is part of the process rather than an outcome in and of itself. This conceptualization allows us to introduce a typology that distinguishes two different types of GPGs: final GPGs and intermediate GPGs:

1. Final global public goods are outcomes rather than 'goods' in the standard sense. They may be tangible (such as the environment or the common heritage of mankind) or intangible (such as peace or financial stability).
2. Intermediate global public goods, such as international regimes, contribute towards the provision of final global public goods (Kaul et al. 1999).

As there is no supranational authority that can ensure the provision of GPGs, the implications of globalization include the need for increased transnational cooperation and partnerships, as well as greater intersectoral action. Intermediate GPGs (see Box 3.8.2), like international norms, agreements and regulations, play an important role in this dynamic (Kaul et al. 2003; Fidler 2002; Taylor et al. 2003). The WHO FCTC provides an example of an intermediate GPG. As an intermediate GPG, the WHO FCTC establishes a basis

Box 3.8.2 Intermediate global public goods

Instruments that contribute to the provision of final global public goods.

Box 3.8.3 Final global public goods

Outcomes that can be tangible (such as the environment or the common heritage of mankind) or intangible (such as peace or financial stability).

for coordinated action among states, which will bring about a significant health improvement not otherwise efficiently obtainable by states acting on their own (Taylor et al. 2003).

Using the intermediate GPG of international law to achieve the final GPG of health

Using international law to produce health, the goal and final GPG (see Box 3.8.3) of international health instruments, comprises four essential aspects. First, states use international law to establish formal institutions empowered to work on global public health problems. The modern classic example of this is, of course, WHO itself, but it is reasonable to also include certain others, such as the United Nations Environment Programme (UNEP) and the International Labor Organization (ILO), that also, if somewhat indirectly, promote and foster health.

Second, states use international law to establish procedures through which states and non-state actors can tackle specific global public health problems. For example, to effectively address the transnationalization of health risks and diseases, instruments like the WHO FCTC and the International Health Regulations (IHR) provide frameworks for efficient multilateral information and surveillance systems. Implementation and ongoing evolution and improvement of these systems are critical, and the complexity inherent in this kind of information gathering is exemplified by WHO's strengthening global monitoring and alert systems, which link together, *inter alia*, specialized laboratories, disease surveillance systems, sources of relevant expertise, and state governments via electronic and printed media.

Third, states use international law to craft substantive duties in connection with particular global public health challenges. The IHR, for example, obligate WHO Member States to notify the Organization of specific public health events. The WHO FCTC requires Parties to implement specific obligations like adhering to a discrete tobacco product labelling and warning regime, as well as to incorporate the general obligations and objectives of the Convention into their approaches to providing health.

Fourth, states use international law to create mechanisms to enforce substantive legal duties undertaken by states that have agreed to be bound by international instruments. Enforcement mechanisms come in many forms, from states self-reporting on progress made in connection with certain goals articulated in a treaty, as is common in multilateral environmental agreements like the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal (1992), to formal adjudication of state-to-state disputes by an international tribunal, as seen in the WTO's dispute-settlement mechanism.

While various instruments can be intermediate GPGs for health, international legal agreements are among the most important. International legal agreements provide a foundation for many other intermediate products with global public benefits, including institutionalized forums for global cooperation, research, surveillance, technical assistance programmes, and information clearing-houses. Global agreements are negotiated to secure global cooperation, and that cooperation, in turn, leads to the sustained creation and promotion of health and related GPGs.

Case studies

The intermediate GPGs that comprise health-related international normative agreements, strategies, and instruments will improve public health, reduce the burden of disease, and lead to reductions in poverty and increases in economic development. Globalization has been a cardinal factor triggering the expansion of international health law and has compelled the international community to think creatively and to develop new models of cooperation, including the expanded use of international health law, to protect and promote the health of populations worldwide. The five case studies that follow illustrate the relevance of norms, standards, agreements, and regulations in transnational disease control and discuss the impact of such instruments now and in the future.

Case study: the WHO Framework Convention on Tobacco Control

The WHO FCTC is a carefully balanced legal instrument, adopted following vigorous negotiations, which took into account scientific, economic, social, and political considerations. The launch of WHO's first treaty negotiation was catalysed by a unique convergence of a number of factors, including the accumulation of scientific evidence demonstrating the causal links between tobacco use and more than 20 major categories of disease (Doll 1998), and evidence pointing to the global toll of tobacco-related diseases, the release as a result of litigation in the United States of over 35 million pages of previously secret tobacco industry documents, which provided a unique opportunity to better understand the strategies and tactics of the tobacco industry and, in doing so, to advance the public health agenda (Yach and Bettcher 2000), the establishment of a WHO cabinet project, the Tobacco Free Initiative, and the support of civil society in the form of public pressure on governments for strengthened tobacco regulations as the public became more aware of the dangers of tobacco (Da Costa e Silva and Nikogosian 2003).

The WHO FCTC is the first treaty negotiated under the auspices of WHO. As such, it is a milestone in public health and it provides new legal dimensions in international health cooperation. This case study explores the status of the WHO FCTC, demonstrates how the provisions of the Convention promote evidence-based interventions that have been proven to be effective, and finally discusses how the WHO FCTC is an intermediate GPG for health.

Fast-paced ratification

The WHO FCTC entered into force on 27 February 2005 when it had 40 Parties, only about one and a half years after it had been opened for signature (WHO 2003c). Those 40 rapidly grew to 177 in 2013. The WHO FCTC now covers about 90 per cent of the world's population (see Fig. 3.8.1).

Key provisions of the WHO FCTC

The Convention includes a number of provisions regarding demand- as well as supply-reduction measures. Key provisions also include obligations to establish or reinforce a national coordinating mechanism for tobacco control, to protect public health policies with respect to tobacco control from interests of the tobacco industry and to consider taking legislative action to address liability, including compensation. In addition, the Convention addresses international cooperation as well as reporting and the exchange of information.

Demand-reduction measures

Price measures

Price and tax measures are an important and effective means of reducing tobacco consumption—a fact recognized in Article 6. It is estimated that a 10 per cent increase in the price of cigarettes will reduce consumption by approximately 4 per cent in a high-income country and by approximately 8 per cent in a low- or middle-income country (World Bank 1999). Furthermore, it has been shown that tax increases have a stronger impact on young people, which is particularly important, as the risk of lung cancer increases exponentially with the duration of smoking. Lastly, increases in tobacco taxes increase government revenue.

Non-price measures

Protection from exposure to tobacco smoke. Article 8 of the WHO FCTC requires Parties to provide 'for protection from exposure to tobacco smoke in indoor workplaces, public transport, indoor public places and, as appropriate, other places' (WHO 2003c).

Packaging and labelling of tobacco products. When warning labels contain large, graphic, thought provoking, and factual information, they are effective in deterring tobacco use. Article 11 obliges Parties to appropriately label packages of tobacco products. Tobacco product label warnings are unique in prevention because the consumer receives the warning at the time of use.

Education, communication, training, and public awareness. In Article 12, Parties are required to adopt legislative or other measures that promote public awareness and access to information on the dangers of tobacco.

Tobacco advertising, promotion, and sponsorship. Article 13 requires each Party to undertake comprehensive bans of all tobacco advertising, promotion and sponsorship, as far as constitutionally possible for each Party.

Article 14 requires Parties, for example, to create cessation programmes, including in workplaces, educational institutions, and other settings; and to include diagnosis and treatment of nicotine dependence in national health programmes.

Supply-reduction measures

In Article 15, the WHO FCTC recognizes that the elimination of smuggling and all forms of illicit trade in tobacco products is an essential component of tobacco control. The first Protocol to the WHO FCTC builds upon and complements Article 15.

Further supply-reduction measures in the WHO FCTC include measures to protect minors (Article 16) and to provide support for economically viable alternatives to tobacco growing (Article 17).

Treaty bodies

The Convention's main treaty bodies, the Conference of the Parties (COP) and the Convention Secretariat, have been established and

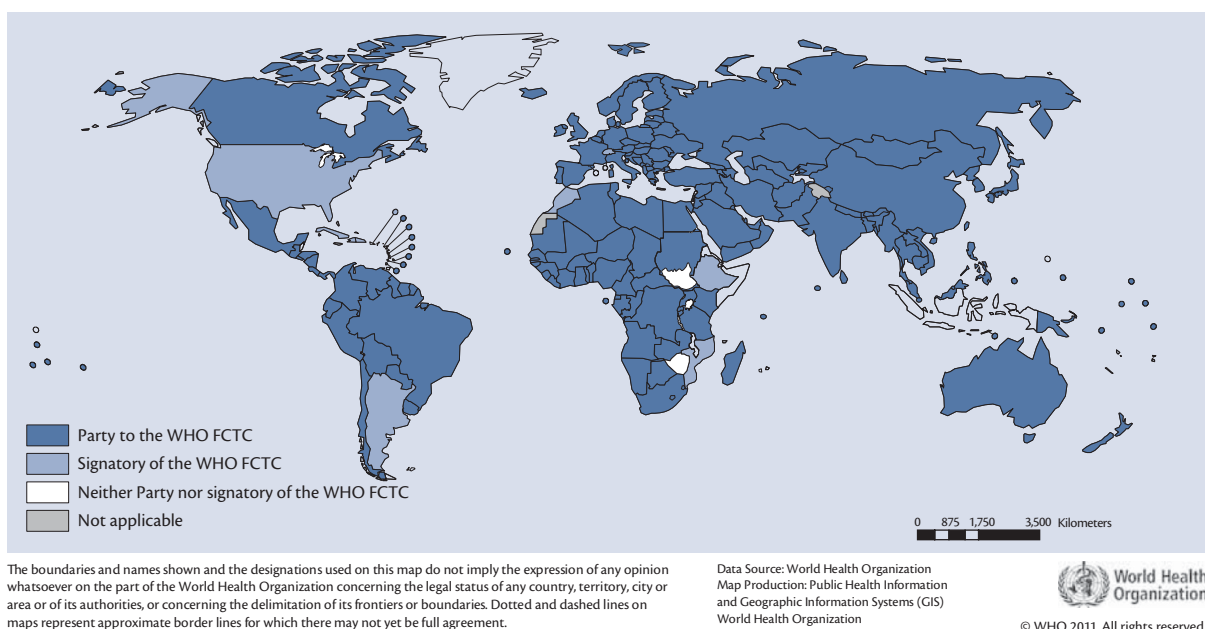

Fig. 3.8.1 Parties to the WHO Framework Convention on Tobacco Control (FCTC).

Reproduced with permission of the World Health Organization, Copyright © 2011

are fully functional (Nikogosian 2010). The governing body of the WHO FCTC, the COP, now meets every 2 years. Starting from its second session, Parties have been hosting this global public health event. The first COP (COP1) was held in 2006 in Geneva, and subsequent sessions were hosted by Thailand, South Africa, Uruguay, and the Republic of Korea (COP 2007, 2008, 2010, 2012). The sixth session of the Conference was hosted by the Russian Federation (COP 2014).

Treaty instruments

One notable development is the rapid development of treaty instruments, namely implementation guidelines and the first Protocol.

Article 7 of the WHO FCTC obliges the COP to propose ‘appropriate guidelines for the implementation...of’ the non-price measures to reduce the demand for tobacco products. The COP has met this obligation by adopting guidelines for Articles 8 (COP 2007), 11, 12, and 13 (COP 2008 and 2010). Partial guidelines for Articles 9 and 10 have been adopted and remain work in progress (COP 2006, 2007, 2008, 2010, 2012). Although not directly referred to in Article 7, the Parties also adopted guidelines for Articles 5.3 and 14 (COP 2008 and 2012). The COP’s initiative to elaborate guidelines on Article 5.3 corresponds with the large extent of interference of the tobacco industry experienced by Parties while implementing the WHO FCTC (COP 2012; WHO 2012a).

In addition, guidelines and policy options are being developed for Articles 6, 17, and 18 (COP 2012) and the COP also established an intergovernmental working group on sustainable measures to strengthen the implementation of the WHO FCTC (COP 2012). Therefore, the COP adopted guidelines and established processes for further instruments for the majority of substantive articles of the WHO FCTC in the brief period between 2006 and 2012.

Reporting system

Under Article 21, Parties have an obligation to submit periodic reports on the status of implementation to the COP. The reporting system was established and refined quickly; it is now functional and synchronized with the biennial cycle of the COP. More than 90 per cent of Parties submitted at least one implementation report after the entry into force of the Convention (WHO 2012a). The Secretariat regularly issues global progress reports based on the reports submitted by Parties. The latest report was issued in 2012, with plans to publish new reports every 2 years.

International cooperation and assistance

The importance of implementation assistance to Parties has risen steadily. Constraints and barriers encountered by Parties are manifold (WHO 2012a) and require adequate assistance. A range of mechanisms of assistance and international cooperation modes were systematized and promoted by the COP and in the UN system. Based on Article 26, a database of resources available to support the implementation of the Convention was created. Needs assessment exercises are carried out in many Parties jointly between the government and the Convention Secretariat, also involving the respective WHO office and relevant UN agencies and other international partners. The integration of the WHO FCTC in national health and development programmes has emerged as a central mechanism in implementation assistance. The role of the WHO FCTC has also been highly recognized in the action against the growing burden of non-communicable diseases (NCDs) as stated in the ‘Political Declaration of the High-level Meeting of the General Assembly on the Prevention and Control of NCDs’ (United Nations 2012).

In a recent decision, the United Nations Economic and Social Council (ECOSOC) called for UN system-wide coherence on tobacco control. In particular, it encouraged the members of the

Ad Hoc Inter-Agency Task Force on Tobacco Control to promote effective tobacco control policies and assistance mechanisms at the national level, including by integrating WHO FCTC implementation within the United Nations Development Assistance Frameworks (ECOSOC 2012).

Newly adopted treaty: Protocol to Eliminate Illicit Trade in Tobacco Products

The COP recognized that ‘cooperative action is necessary to eliminate all forms of illicit trade in tobacco products’ and established the Intergovernmental Negotiating Body (INB), mandated with negotiating a protocol (COP 2007).

The INB held five sessions between 2008 and 2012. The absolute majority of WHO FCTC Parties participated in the negotiating sessions. At its fifth session, the INB agreed on a draft text of a protocol to eliminate illicit trade in tobacco products. The Protocol was adopted on 12 November 2012 at the fifth session of the COP in Seoul (COP 2012).

The Protocol comprises a variety of obligations, namely the Supply Chain Control, including the establishment of a licensing system, an international tracking and tracing regime, due diligence, provisions for free zones, duty free sales, and the sale by Internet. In addition, the Protocol aims to protect personal data and addresses unlawful conduct including criminal offences, ‘seizure payments’, the disposal of confiscated products, information sharing, assistance and cooperation, mutual legal assistance and reporting.

One of the lessons learned during the negotiations was that one way to reach consensus on a controversial matter is to refer it to the governing body. For example, the Protocol refers two technical matters to its governing body, the Meeting of the Parties (MOP): whether key inputs exist and the extent of illicit trade related to duty free sales (WHO 2013b).

The Protocol includes time-bound provisions. Within 5 years of entry into force, Parties have to establish a global tracking and tracing regime (WHO 2013b). Each Party has to ensure that ‘unique identification markings’ are affixed to packets and outside packaging of cigarettes within 5 years and other tobacco products within 10 years of entry into force of the Protocol for that Party (WHO 2013b). Regarding free zones, Parties have to control the manufacture and transactions in tobacco and tobacco products within 3 years of entry into force (WHO 2013b).

The infrastructure established under the WHO FCTC is used for the Protocol—this concerns the rules of procedure and financial rules of the COP, the reporting being incorporated into the COP reporting, and the sessions of the MOP to be held back-to-back with those of the COP (WHO 2013b).

Impact of WHO FCTC

The implementation of the Convention already demonstrated its impact on national legislation. One key conclusion of Parties’ reports is that following ratification, 80 per cent of Parties either adopted new tobacco control legislation or strengthened existing legislation (Fig. 3.8.2). The COP decided at its fifth session that an impact assessment, linked to the tenth anniversary of the entry into force of the Convention in 2015, should be carried out.

Empirically, increasing the price of tobacco products is a strong measure to curb consumption. The potency of this measure is clear in economic terms: a 33 per cent increase in the price of tobacco would yield a cost-effectiveness ratio of US \$3 to \$42 for

every disability-adjusted life year (DALY) averted in low- and middle-income countries, and of US \$85 to \$1773 in high-income countries (Jamison et al. 2006). An averted DALY has sizeable financial implications, with less public and private expenditure on healthcare for tobacco-attributed illnesses. And contrary to critics’ fears, taxation on tobacco products actually raises government revenues because consumption usually falls at a slower rate than price increases (Frank et al. 2000).

The implementation of price and other strong measures are linked with public health and broader economic gains, with positive implications for long-term development. The treaty also serves as a legal resource and catalysed strong movement to address the growing burden of NCDs worldwide.

The WHO FCTC as an intermediate global public good for health

The WHO FCTC and the process of negotiating the WHO FCTC both have important intermediate GPG characteristics. The Convention and its negotiation are intermediate GPGs in that both have facilitated the development of tobacco control policies globally (Taylor et al. 2003). The WHO FCTC facilitates the flow of information about tobacco control and serves as a mechanism to coordinate various transnational aspects of tobacco control, including smuggling, advertising, packaging, and labelling. It enhances global surveillance, information exchange, and international technical, legal, and financial cooperation in tobacco control. The WHO FCTC process continues to provide a global instrument for public health professionals to distribute their evidence to governments and to get this evidence incorporated into binding agreements including future protocols to the Convention. Overall, it provides new legal dimensions for international health cooperation.

Conclusion: the WHO Framework Convention on Tobacco Control

The strength of the WHO FCTC resides in several elements. First, it is an evidence-based treaty. All the tobacco control measures required by the WHO FCTC have been proven to be effective and are based on numerous experiences and facts. Second, it is a comprehensive tool that addresses all the effective tobacco control policies that can be implemented to reduce tobacco consumption; its effect will exceed the sum of the results of each measure taken separately because some measures increase the effectiveness of others. Third, the process of developing the Convention showed how the growing role of transnational factors in health can be addressed through a legally binding instrument, a new direction in international health. Fourth, the Convention demonstrated its attractiveness as a new type of global public health instrument—more than half of States ratified it within less than three years of entry into force, and the absolute majority had done so by 2012. Fifth, Parties displayed high commitment in the implementation of the Convention, including by promptly establishing the principal treaty instruments, such as guidelines, the reporting system, the mechanisms of assistance and the first protocol to the WHO FCTC. Finally, the years after the entry into force have shown growing political recognition of the role of the WHO FCTC on the global health and development agenda, including in the UN system.

The WHO FCTC provides a legal framework for improving the health of all people. It is a model for an effective global response

Fig. 3.8.2 Adoption of legislative, executive, administrative, and other measures in relation of ratification of the WHO FCTC.

to the negative effects of globalization on health. However, the Convention remains a tool and its success depends on governments' dedication to making the best use of it (Nikogosian 2010).

Case study: the International Health Regulations (2005)

The International Health Regulations (2005) (hereinafter 'IHR' or 'the Regulations') are an instrument of international law adopted by the World Health Assembly, WHO's supreme decision-making body,² on 23 May 2005 under Article 21 of the WHO Constitution. They entered into force, generally, on 15 June 2007 and are legally binding on 196 States Parties, including all WHO Member States. The Regulations apply to emerging infectious diseases like SARS and pandemic influenza, as well as to those cross-border threats that arise as a result of public health risks and emergencies whose origin may be biological, chemical or radiological in nature. The 2011 nuclear accident in Fukushima, Japan, is an illustration of how the IHR may apply to an event which is not biological in nature. The stated purpose and scope of the Regulations are to prevent, protect against, control, and provide a public health response to the international spread of disease in ways that are commensurate with and restricted to public health risks, and which avoid unnecessary interference with international traffic and trade. In order to fully appreciate their broad scope, however, it is necessary to refer to key terms, which are defined in the IHR, including event, disease, public health risk, public health emergency of international concern and international traffic (WHO 2005). This case study describes experiences and progress in implementing the IHR in States Parties with the support of the WHO Secretariat with a view to showing how the Regulations may, in part, be considered an intermediate GPG for health.

The IHR as an intermediate global public good for health

The concept of public goods and what makes them global have been defined and discussed elsewhere in this chapter. Relevant to the examination of the IHR, disease control at the national level through the adoption of regulatory measures can be seen as a public good for health. That is, such a public good is non-excludable

because it benefits those who are not even aware that there is a risk (of disease) and non-rivalrous due to the fact that one person benefiting from disease control does not prevent another from also benefiting. With regard to the global nature of the public good of infectious disease control it is clearly the intent of the IHR to be a transboundary, globally inclusive instrument. Article 3 (Principles) of the 2005 IHR provides that the implementation of the new rules 'shall be guided by the goal of their universal application for the protection of all people of the world from the international spread of disease' (WHO 2005).

In terms of the IHR as an intermediate GPG for health, the freedom from epidemics (or epidemic control) is a final GPG for health, while the surveillance and control mechanisms required to attain this goal are an intermediate GPG for health. A functioning IHR provides the set of rules that establish administrative and legislative structures in support of these intermediate GPGs for health. Therefore, inasmuch as they deal with epidemic control, the IHR may constitute an intermediate GPG for health. Although it remains difficult to assess the extent to which the IHR will be an effective tool to curb epidemics, it is clear that its purpose and scope continue to make it a strong candidate as an intermediate GPG for health.

As is shown by the monitoring framework developed by WHO (see later) to assess progress in implementing the IHR, the Regulations' coverage is considered broad enough to encompass relevant public health risks involving biological, chemical, or radiological agents (WHO 2007b). It is also important to reiterate that the IHR are designed to contain the international spread of disease while at the same time ensuring that the international movement of people and goods is not unnecessarily restricted. This nexus between public health and international traffic, as well as between the law of infectious disease and trade law, continues to be an important and defining aspect of the Regulations.

Strengthening capacities for IHR implementation

A major focus of IHR implementation has been to support States Parties to strengthen existing surveillance and response capacities. Indeed, according to Article 5 and 13 of the Regulations, IHR States Parties have 5 years from entry into force (i.e. 15 June

2007) ‘to develop, strengthen and maintain the capacities to detect, assess, notify and report events’ (to WHO) and ‘to respond promptly and effectively to public health risks and public health emergencies of international concern’, as set out in Annex 1. The 5-year period for developing, strengthening or maintaining these capacities expired for most IHR States Parties on 15 June 2012. It is important to highlight that under the IHR, States Parties that have not met their capacity requirements may apply for and obtain a further 2-year period to establish them (i.e. through 15 June 2014) based on a justified need and upon presentation of an implementation plan. To date, more than one-half of IHR States Parties have obtained such an extension.

A key issue in applying for extensions is the progress States Parties have made to implement the Regulations and how this progress has been measured. Moreover, under Article 54 of the IHR and World Health Assembly resolution WHA61.2 (WHO 2008), States Parties must report to the Assembly, WHO’s supreme governing body, on progress made in implementing the Regulations. To assist countries to assess this progress and meet this reporting requirement, WHO has developed a monitoring framework with eight core capacities for tracking IHR implementation: (1) national legislation, policy, and financing; (2) coordination at national level and the communication of National IHR Focal Points,³ both globally and nationally; (3) surveillance; (4) response; (5) preparedness; (6) appropriate communication of risks; (7) human resources; and (8) adequate laboratory services. The framework also defines five relevant hazard types: (1) infectious, (2) zoonotic, (3) food safety-related, (4) chemical, and (5) radionuclear (WHO 2011a). In line with this framework, States Parties are annually requested to complete a self-assessment questionnaire. The latest questionnaire from 2012 has garnered the following summary results based on 127 (of 195) responses (WHO 2013c): progress has been made with respect to surveillance (with a global average score of 81 per cent), response (78 per cent), and zoonotic events (80 per cent). Low capacities were reported for human resources (with a global average of 53 per cent), chemical events (51 per cent), and radiological events (53 per cent). In addition to the self-assessment questionnaire, a number of IHR States Parties have requested WHO to conduct assessment missions and conduct desk audits to, *inter alia*, identify gaps and develop action plans for IHR implementation through 2014 (WHO 2013c).

Evaluating the functioning of the IHR and pandemic influenza (H1N1) 2009

On 25 April 2009, the WHO Director-General determined that the ongoing human influenza event in Mexico and the United States of America constituted a public health emergency of international concern⁴ (WHO 2009). This was the first time (and the only time to date) since the entry into force of the Regulations that such an international emergency had been declared by the WHO Director-General.⁵ This determination was an important step because until that date a host of IHR provisions had not been tested since PHEICs are (almost by definition) rare occasions and in ‘peace time’ the Regulations are applied on a daily basis to other types of public health events, risks and emergencies that do not reach the ‘PHEIC’ threshold, as determined by the Director-General. The significance of this event as relates to the IHR as GPG for health is that, in the aftermath of the pandemic,

concerns were raised that the IHR, the WHO and the world community had not met up to their expectations and that there was a need to draw lessons from this unique experience. In addition to this, under Article 54 of the IHR, the Health Assembly is required to review the *functioning* of the IHR and this review must take place ‘no later than five years after the entry into force of these Regulations’. The timing of this review was further decided by the Health Assembly in resolution WHA61.2. Article 54 also provides that this review may be conducted with the advice of a Review Committee to be convened by the Director-General. In 2010, WHO’s Executive Board⁶ welcomed the proposal of the WHO Director-General to establish such a Committee whose objectives were to: (1) assess the functioning of the IHR, (2) assess the ongoing global response to pandemic (H1N1) 2009, and (3) identify lessons learned important for strengthening preparedness and response for future pandemics and public-health emergencies (WHO 2011b). With regard to the first objective, a major conclusion of the Review Committee was that the IHR had ‘helped make the world better prepared to cope with public-health emergencies’. This optimistic finding, however, was immediately followed by this statement: ‘The core national and local capacities called for in the IHR are not yet fully operational and are not now on a path to timely implementation worldwide.’ Judging from the number of States Parties seeking and obtaining extensions to establish these capacities by 2014 the Review Committee’s conclusion on this point still holds true.

Conclusion: the International Health Regulations (2005)

The IHR have shown their potential to become an intermediate GPG for health. Their purpose of preventing and protecting against the international spread of disease, including epidemic control, while avoiding unnecessary interference with world traffic, continues to fall within the definition of a public good. Moreover, the global nature of this public good is clear, given the Regulations’ textual intent of universal application. Regarding the IHR’s enabling role as an intermediate GPG for health, implementation of the Regulations has met with mixed results. Although States Parties are highly committed to implementing the IHR (WHO 2012b), the necessary resources to achieve this have been hampered by the current economic and financial climate. This has resulted in an intensified effort by WHO to galvanize States Parties and to match their needs with the priorities of partners and stakeholders, including the donor community, the common goal being to lend their support to ensure that the number of countries that have obtained extensions to the 2012 deadline will be significantly reduced by June 2014. Finally, although not within the scope of this case study, a recurring debate surrounding IHR implementation is the question of its contribution to the at times nebulous concept of global (public) health security (WHO 2007b), which could itself be seen as a potential GPG for health candidate.

Case study: food safety—the Codex Alimentarius Commission and the International Food Safety Authorities Network

Food safety and food control have been recognized as important issues for decades. The rapid globalization of food production

and trade has increased the potential for international incidents involving contaminated food. As a result, international monitoring and control as well as rapid exchange of information in case of emergencies need to be improved. Many major initiatives both in safe food production and in monitoring and control have contributed to improving food production systems and to the prevention of food-borne disease in most developed countries. But serious outbreaks of food-borne disease have been documented on every continent in the past decade, illustrating the public health implications and social significance of unsafe food. Additionally, recent incidences have shaken the consumers' trust in food safety systems. Bovine spongiform encephalopathy (BSE), dioxin, melamine, *Escherichia coli* O157, *Salmonella*—all food-borne hazards that were virtually unknown 10–15 years ago—are now household names in most families.

Food-borne diseases not only significantly affect people's health and well-being, they also have economic consequences for individuals, families, communities, businesses, and countries. These diseases impose a substantial burden on healthcare systems and markedly reduce economic productivity. The loss of income due to food-borne disease perpetuates the cycle of poverty. Estimating direct as well as indirect costs of food-borne disease is difficult. An estimate in the United States places the medical costs and productivity losses in a population of approximately 250 million in the range of US \$6.6–37.1 billion (Buzby and Roberts 1997).

Global improvement to assure a safe and sufficient food supply requires a strategic approach, in strengthening national food safety systems, fostering and formalizing a strong cross-sectoral approach linking the agriculture, veterinary, and public health sectors, and implementing evidence-based measures along the food chain to reduce food-borne health risks. One of the primary multilateral responses to the need for internationally harmonized food safety management is the Codex Alimentarius Commission (CAC), an intergovernmental body formed in 1963 that operates under the joint auspices of the Food and Agriculture Organization of the United Nations (FAO) and WHO. The objective of the CAC is to protect the health of consumers and to ensure fair practices in the food trade, while promoting coordination of all food standards work undertaken by intergovernmental and non-governmental organizations (FAO and WHO 2006, 2007). The international food standards and related texts adopted by CAC constitute the Codex Alimentarius (Codex). All food standards and related texts in the Codex are voluntary and become binding only when they are converted into national legislation or regulation. Membership in the CAC is open to all member nations and associate member nations of FAO and WHO, and currently covers more than 99 per cent of the world population.

Despite improved food safety systems in many parts of the world, the occurrence of food contamination events cannot be avoided. In response to the 2000 WHA resolution on food safety and to address the need for rapid access and exchange of information in case of a food contamination event of international concern, the International Food Safety Authorities Network (INFOSAN) was established. INFOSAN provides tools and support to increase Member States' capacity to respond to health emergencies posed by natural, accidental, and intentional contamination of food.

This case study examines the global burden of food-borne disease and provides overviews of CAC and INFOSAN, the most salient international responses to food safety concerns. As part

of the review of these mechanisms, the question of the CAC and INFOSAN providing intermediate GPGs for health is considered.

Food-borne disease burden

Food-borne and water-borne diarrhoeal diseases kill an estimated 2.2 million people annually, most of whom are children. While diarrhoea is the most common immediate symptom of food-borne illness, other serious consequences include kidney and liver failure, and brain and neural disorders. Food contamination also contributes to the burden of NCDs, in particular cancer and cardiovascular diseases, and can also affect reproductive health and the immune system.

Further, diarrhoeal diseases only constitute a fraction of disease caused by food. Microorganisms transmitted through food can cause many other types of disease, including very serious long-term infections. Even more important, the disease burden caused by chemical hazards in food is largely unknown. Therefore, determinations of the impact of food-borne disease have always relied heavily on estimates and assumptions. To address this lack of knowledge, WHO has started to estimate the global burden of food-borne disease, taking enteric, parasitic and chemical hazards into account, and it is expected to have a broader knowledge base on the global burden of food-borne illness in the near future.

The risk of spread of food-borne diseases is greatly increased with increasing global trade of feed, food ingredients, partially processed food, and final food products. International travel also represents a significant source of food-borne disease for some countries. For example, in 2005, Sweden reported that 80.2 per cent and the Netherlands reported 87 per cent of their salmonellosis cases acquired their infection while overseas (EFSA 2007). It has become imperative to address the matters related to food safety and quality at the international level—to complement and assist the actions taken by national governments that carry the primary responsibility to ensure food safety for their population.

The Codex Alimentarius Commission

Legal basis and organizational structure

The CAC was established as a joint commission, to be the executive organ of the Joint FAO/WHO Food Standards Programme. The CAC enjoys certain autonomy on procedural and programmatic matters, whereas the strategic direction of the Joint Programme is laid out by the Member States in the respective governing bodies of the two parent organizations. The highest governing body of the Codex is the Commission. The CAC Secretariat is located at FAO headquarters in Rome and supports the work of the CAC and its subsidiary bodies.

The preparatory work of the Codex (i.e. development of draft international standards and related texts), is undertaken by the subsidiary bodies of the CAC; namely, Codex committees and task forces. They are classified into two categories: (1) general subject committees that address horizontal aspects of food standards (additives, contaminants, pesticide and veterinary drug residues, labelling, hygiene, nutrition, methods of analysis and sampling, etc.); and (2) commodity committees that address specific groups of commodities (fish and fishery products, milk and milk products, fats and oils, etc.).

Codex Standards, in particular safety standards, are based on independent scientific advice provided through international expert committees convened by FAO and WHO, including: Joint FAO/WHO Expert Committee on Food Additives (JECFA),

Joint FAO/WHO Meetings on Pesticide Residues (JMPR) and Joint FAO/WHO Expert Meetings on Microbiological Risk Assessment (JEMRA). Ad hoc expert meetings are convened to address emerging and emergency issues, such as the 2008 melamine contamination of the global food supply.

Operations and procedure

The operation of the Codex system is guided by the Rules of Procedure, adopted by the Commission and endorsed by the Directors-General of FAO and WHO. The process of elaboration and adoption of international standards and related texts follows a procedure consisting of eight steps.

- ◆ Step 1: a proposal for new work is reviewed and a decision on whether or not to undertake new work is taken by the Commission.
- ◆ Steps 2, 3, and 4: a draft text is prepared and circulated to governments and all interested parties for comment, followed by review by the relevant Committee.
- ◆ Step 5: the Commission reviews the progress made and agrees that the draft should go to finalization.
- ◆ Steps 6 and 7: the approved draft is sent again to governments and interested parties for comment and is finalized by the relevant Committee.
- ◆ Step 8: following a final round of comments, the Commission adopts the draft as a formal Codex text.

An accelerated procedure whereby the elaboration of a text is concluded by adoption at Step 5/8 can be used, thereby skipping steps 6 through 8. Increasing application of this accelerated procedure has led to a significant increase of adoption of standards, particularly in the area of pesticide and veterinary drug residues in food.

International importance

The Codex system has become the global reference point for consumers, food producers and processors, national food control agencies, and the international food trade. Codex standards are recognized in the World Trade Organization's (WTO) Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement) and the Agreement on Technical Barriers to Trade (TBT Agreement), and have become the benchmarks against which national food measures and regulations are evaluated within the legal parameters of the WTO Agreements.

In particular, the SPS Agreement specifically designates Codex standards, guidelines, and recommendations as the international benchmark in food safety, with which WTO members are encouraged to harmonize their sanitary measures. The SPS Agreement acknowledges that governments have the right to take sanitary measures necessary for the protection of human health. WTO members applying measures that deviate from Codex standards are allowed to do so but are required to provide scientific justification based on risk assessment for such measures.

The International Food Safety Authorities Network

In collaboration with FAO, WHO initiated the International Food Safety Authorities Network (INFOSAN) in 2004. Recognizing the continuous increase in global food trade and travel, INFOSAN was developed to share food safety information and experience, as well as to promote collaboration between food safety authorities at national and international levels. An

integral part of the INFOSAN network is the rapid exchange of emergency information between such authorities relative to food safety events or emergencies. This is known as INFOSAN Emergency.

As of May 2013, INFOSAN has 181 member countries and is advised on its strategic functions by an external advisory group. Non-emergency related activities include sharing experience and best practices between members and the publication of INFOSAN Information Notes, describing the latest food safety knowledge. Multilateral communication is also encouraged as a means of countries learning from each other's experiences, facilitated through a closed, web-based communication platform.

INFOSAN Emergency operates within the International Health Regulations (2005) (WHO 2005) and oversees all food safety related events in close cooperation with IHR focal points, inclusive of food contamination and food-borne disease. On average, 200 food safety events per month are investigated to determine their public health impact, including events of unusual or unexpected natures, distribution, and possible trade restrictions. The network actively shares information about one or two such events per month deemed of international public health significance. For example, when two shigellosis outbreaks occurred in two countries both implicating baby corn from a third country, INFOSAN Emergency sought information from the exporting country. Through this process it was determined that a further three countries were at risk since they had imported the affected baby corn. INFOSAN Emergency alerted all three countries, enabling a process where these countries could determine the risk for their population and implement their own appropriate risk management options.

Membership in INFOSAN is voluntary. However, the legal obligation with regard to INFOSAN Emergency is a mix of both hard and soft law: the 2005 IHR (hard law) and the instruction to WHO to maintain a list of primary contacts from the CAC (soft law). FAO and WHO encourage the rapid notification of food safety events or emergencies associated with traded foods to international bodies and to the INFOSAN network.

The Codex and INFOSAN as intermediate GPGs for health

Both the Codex and INFOSAN have proven capacity to improve health and health systems, the predicate for an intermediate GPG for health. The success of CAC as the multilateral framework for global food safety is the result of the global scale and scope of a large number of commodity standards and safety standards covering the farm-to-table approach. In addition many consider the Codex a successful UN initiative because of a high level of transparency and inclusiveness ensured by the participation of a large number of governmental and non-governmental observer organizations in the eight-step rule-based standards-setting process, and the fact that the safety standards are evidence-based.

In 2012, the CAC adopted close to 500 standards based on scientific assessments:

- ◆ 27 maximum residue limits (MRLs) for veterinary drug residues.
- ◆ 270 MRLs for pesticide residues in specified crops.
- ◆ 165 maximum use levels for food additives in specified food categories.

- ◆ Two maximum limits for contaminants (melamine and aflatoxins).
- ◆ Two food hygiene standards.

Contributing to the success of Codex is the FAO/WHO Project and Fund for Enhanced Participation in Codex (known as the Codex Trust Fund). The Codex Trust Fund was established to enhance participation in Codex by developing and transition economy countries by: (1) providing support to allow delegates of eligible countries to attend Codex meetings, (2) supporting Codex training courses and workshops to build capacity for more effective participation in Codex, and (3) supporting scientific and technical input from eligible countries into the Codex process.

INFOSAN has demonstrated its function as an intermediate GPG for health, strengthening international as well as national food safety systems and providing a platform for the development of the GPG of health, itself. The provision of INFOSAN Information Notes provides technical support for national food regulators when considering the impact and management of evolving food safety issues. INFOSAN Emergency activities enable rapid alerts to countries about food safety events or emergencies that may impact both the health and the economy of these countries. INFOSAN also assists national governments with the necessary public health response as required.

Conclusion: food safety

The ability of national governments to regulate food safety as they simultaneously move to increase food security presents many challenges. Food production systems need to be improved and these improvements should be informed by the lessons learned through food safety mistakes. When confronted with growing levels of international food trade, cross-border competition, increasing corporate and supplier power, and rapid consolidation of global agrifood markets and industries, governments recognize that the domestic food systems cannot be regulated unilaterally. Consequently, there is increased interest in and support for collective policy action at the multilateral level to protect citizens and to achieve the collective good.

Case study: Pandemic Influenza Preparedness Framework

Humanity has confronted infectious pathogens that cause epidemic or pandemic disease since its origins. Of all the microorganisms that have resulted in outbreaks of deadly disease, among the most deadly in human history is the Orthomyxoviridae family of viruses, known commonly as influenza. This family of viruses is characterized by its capacity to change into new, sustainably transmissible viruses to which humanity has little or no pre-existing immunity. Those new viruses are called pandemic influenza viruses.

One of the most lethal influenza viruses in the recent past was the 1918 A(H1N1) virus which, according to epidemiological estimates, caused 20–50 million deaths worldwide. While the advent of post-Second World War medicine, including improvements in vaccine production and technology, may have allowed the fear of pandemic flu to recede in the public mind, apprehension among public health experts about another 1918-like flu event has never waned. Indeed, concern over the continued threat posed by

influenza prompted WHO, very soon after its creation in 1947, to establish the first truly global network of laboratories to gather and monitor flu viruses, assess attendant risks and, eventually, coordinate the selection of strains for vaccines.

That network, which has since become known as the Global Influenza Surveillance and Response System (GISRS), operated for decades receiving little, if any, attention outside of public health circles. However, the appearance of the severe acute respiratory syndrome (SARS) coronavirus—a virulent viral pathogen—around 2003, and a spike of concern about the A(H5N1) influenza virus, known commonly as bird flu, in 2005, renewed awareness of the potentially devastating health, economic and social impacts of infectious, pandemic diseases. Suddenly, the existing public health system to address those threats became of intense political interest. And as scrutiny increased, so did interest in improving it.

SARS was extinguished less than 6 months after its detection, and H5N1 has so far not mutated to a form easily and sustainably transmissible among people, but their public health legacies are numerous (Heymann 2012). Among their most direct and potentially far reaching is the 2011 global arrangement known as the PIP Framework, short for the ‘Pandemic Influenza Preparedness Framework for the sharing of influenza viruses and access to vaccines and other benefits’.

The PIP Framework represents the culmination of a 5-year, global effort in public health diplomacy to improve pandemic preparedness and response so that all countries, irrespective of wealth, could access the technologies and products needed to prepare for and protect their populations from flu pandemics.

Influenza-related burden of disease

The WHO-coordinated, international network of laboratories, or GISRS, operates for two principal purposes: (1) to gather representative samples of circulating influenza viruses to conduct detailed risk assessment, including pandemic risk, and (2) to develop candidate vaccine viruses and provide them to influenza vaccine manufacturers for vaccine production.

Influenza is normally a seasonal disease that is well understood in industrialized countries, where awareness of its health and economic impact has prompted governments to develop a vaccination policy that is supported by a well-established and resourced flu-vaccine manufacturing industry. The disease and its burdens, however, are far less well assessed in resource-poor developing states.

The emergence of H5N1 and its potential to trigger a pandemic brought new focus on GISRS and pandemic flu. As the perceived threat of an H5N1 pandemic increased, influenza vaccine manufacturers started to develop and test H5N1 vaccines. Rich and poor countries alike took measures to ensure their future access to vaccines. In a world of limited resources, however, where total pandemic flu vaccine demand far outstrips global production capacity, developing countries found themselves at a significant disadvantage. The precipitating cause of the PIP Framework negotiations was the difficulty for many of these developing countries to secure H5N1 vaccine at affordable prices, or even at all. In a measure that drew attention to this inequitable situation, some developing countries decided to withhold or delay sharing A(H5N1) viruses with GISRS laboratories, denying GISRS access to biological materials that were needed for risk assessment, preparedness, and response. In a number of developing countries, the

question, in effect, was asked: why share the virus if the vaccine produced from it is out of reach?

The need for a more transparent, fair, and equitable system for the sharing of viruses as well as the access to the benefits derived from such virus sharing, namely vaccines and other medical necessities, became pressing. As a result, in May 2007 the 60th World Health Assembly adopted Resolution WHA60.28 requesting the WHO Director-General to, *inter alia*, convene an Intergovernmental Meeting with a view to reforming many of the practices and processes of GISRS and the pandemic influenza preparedness system it supports.

Over the next four years, Member States, with WHO support, worked through the intergovernmental process to develop the PIP Framework.

Overview of the PIP Framework

The PIP Framework has an intentionally narrow scope, covering only the sharing of influenza viruses with pandemic potential (under the Framework, these are known as ‘PIP biological materials’) and the fair and equitable access to benefits derived from such virus sharing. Legally speaking, the PIP Framework is a unique document: although adopted as a resolution of the World Health Assembly, and therefore technically a ‘recommendation’ of that body,⁷ it includes several novelties, including a ‘Partnership Contribution’ mechanism addressed to certain manufacturers, as well as a system to conclude legally binding contracts designed to ensure benefit sharing commitments from both public and private entities.

The structure of the Framework is straightforward: it opens with several Principles that are central to the rest of the text. Following this, after succinct sections on objective, scope and definitions, the Framework addresses three core elements: virus sharing, benefit sharing, and governance. Additionally, annexed to the Framework are five additional and critical instruments: two Standard Material Transfer Agreements; Terms of Reference for the Director-General’s Advisory Group; and Terms of Reference, including a set of Guiding Principles, for the four categories of laboratories in the WHO network.

Principles

The nineteen statements in this section reflect the intensity and breadth of Member States discussions during the 4 years of negotiations. Two principles in particular lend the Framework its distinctive, pioneering aspect. The first places both virus sharing and benefit sharing on an ‘equal footing’, underscoring that they are ‘equally important parts of the collective action for global public health’ (WHO 2011c). Reaching consensus on this provision in December 2008 was the catalyst for breaking 2 years of gridlock over the framing of virus sharing in relation to benefit sharing. It allowed the negotiation of other parts of the Framework to move ahead. Second, benefits are to be made available on the basis of public health risk and need rather than in relation to the level of virus sharing (WHO 2011c). Early in the negotiations, Member States rejected a direct link between virus sharing and access to benefits: benefits were to be made available to countries in need regardless of their contribution of materials to the system. This was considered a critical, ethical principle.

Virus sharing

Responsibility for this activity, which is at the core of the PIP Framework, rests with WHO Member States. Through their duly

authorized or designated ‘National Influenza Centres’ Member States undertake to share with the WHO network material from all cases of infection due to influenza viruses with pandemic potential. Through this, the global scientific community is assured of access to biological materials that are critical for conducting pandemic risk assessment, and that may also be useful in developing vaccines or other medicines to respond to pandemic influenza.

Benefit sharing

Under the PIP Framework, WHO Member States, working with WHO, established a benefit sharing system, which operates to, *inter alia*, prioritize important benefits, such as vaccines, antiviral medicines and diagnostic tools, as high priorities for developing countries, and to secure binding commitments and resources to provide such benefits. The benefit sharing system also operates to build capacity over time, through technical assistance and transfer of technology, skills and know-how to countries in need.

Two innovative tools were developed by Member States to facilitate the successful achievement of the benefit sharing goals of the PIP Framework: an annual cash Partnership Contribution from influenza vaccine, diagnostic and pharmaceutical manufacturers using the WHO network (WHO 2011c) and a legally binding ‘Standard Material Transfer Agreement-2’ (‘SMTA-2’) to be concluded by WHO with all recipients of PIP biological materials outside the WHO network (WHO 2011c).

The Partnership Contribution is one of the most groundbreaking features of the PIP Framework. Addressed directly to manufacturers, this mechanism establishes a link between their use of the WHO GISRS network and a financial contribution to WHO. Each manufacturer’s contribution is based on its individual nature and capacity (WHO 2011c), in accordance with a fully transparent and equitable formula developed with the input of industry and other stakeholders. The resources collected through this mechanism will be used by WHO to improve pandemic preparedness and response (WHO 2011c). It is a novel mechanism for public health and should allow measurable progress in many areas where preparedness is weakest: laboratory and surveillance capacities in developing countries.

The SMTA-2 is another cutting-edge, tailor-made mechanism that addresses the need for real-time access to specific pandemic products—notably vaccines, diagnostic materials and antiviral medicines—at the time of a pandemic. On the one hand, it is a classic contract, binding WHO and the recipient of ‘PIP biological materials’. With respect to the benefit-sharing commitments that may be selected by recipients, however, the SMTA-2 is atypical in its prescriptiveness. The instrument was carefully constructed by Member States to ensure that at the time of a pandemic, countries in need would have real-time access to products necessary for a response. For this reason, the generic SMTA2 which is found in Annex 2 of the Framework provides only six benefit-sharing options from which influenza vaccine and antiviral manufacturers may choose: four of these concern real-time provision of pandemic vaccines and antivirals, and two concern licences to technology relevant to the production of vaccines, adjuvants, antivirals or diagnostics (WHO 2011c). Again, there is no direct, one-for-one link between receipt of PIP biological materials by the recipient and performance of the commitments selected. As long as such materials are received, the selected commitments must be performed. Thus, for example, a vaccine manufacturer that

receives PIP biological materials must provide pandemic vaccines even if a particular production run is not based on those materials. Further, since all recipients of PIP biological materials must conclude an SMTA2, even research and academic institutions are covered, although the benefit sharing requirements addressed to them are far more flexible.

The PIP Framework benefit sharing system, however, is not limited to these two mechanisms. It also promotes more traditional benefit sharing by Member States to, among other things, strengthen laboratory and surveillance capacity, support regulatory authorities, promote technology transfer, and close the gap in the understanding of influenza disease burden in the developing world. This last element is a critical piece of the WHO-led effort to extend seasonal influenza vaccination programmes in the developing world, where epidemiologically warranted. Such seasonal flu programmes are essential to the sustainable functioning of flu vaccine manufacturing capacity, and, consequently, to increasing the global capacity to produce vaccines in the event of a flu pandemic.

Governance

The Framework, given its many novel elements, needed a robust system to advance and monitor its implementation. Its drafters therefore established a three-pillared oversight mechanism, involving the World Health Assembly, the WHO Director-General and a PIP 'Advisory Group'. The overall objective of the oversight mechanism is to ensure effective, efficient, transparent and accountable progress on implementation of the PIP Framework and the achievement of its objectives, both in the short and long terms.

The PIP Framework as an intermediate GPG

As with the other international instruments showcased in this chapter, the PIP Framework and the negotiating process that led to the Framework can both be viewed as intermediate GPGs, in that they 'contribute towards the provision of final global public goods' (Kaul et al. 1999). The PIP Framework increases global and national capacities to address influenza and improves information flow and financial cooperation on matters relevant to pandemic influenza. Additionally, the PIP Framework demonstrably has the capacity to improve health systems and, very like the IHR (2005), at its core is designed to prevent and control the spread of infectious disease. These characteristics, as well as the laboratory, surveillance, and monitoring strengthening that spring from the PIP Framework, allow for a characterization of the Framework as an intermediate GPG for health.

Conclusion: overview of the PIP Framework

The PIP Framework is a unique, forward-looking instrument that provides pragmatic approaches and solutions to address specific public health problems. Its adoption was a landmark achievement, marking a departure from ad hoc pandemic response to a more structured, equitable, predictable, and efficient system for both preparedness and response. Its successful implementation and evolution will depend on many factors, particularly the trust of its many stakeholders in WHO as the body charged with its operationalization. By forging a new *modus operandi* between countries, both developed and developing, and stakeholders, in the public and private sectors, it has strengthened the global community's collective effort to protect all people from the international spread of disease.

Case study: the Minamata Convention: a cross-cutting approach to intermediate GPGs for health

Traditionally, subject areas like international environmental law, trade law, and humanitarian law have been treated as isolated areas of work (Sands 1999). As a result, instruments have often been developed in discrete fora and from discrete vantage points. However, as argued in this and other chapters, there are very few areas that can be conclusively categorized as 'health' or as 'non-health'. Infectious disease control can affect trade and commerce; environmental protection can affect NCD prevalence; and economic or trade decisions can have profound health and environmental impacts. In 2010 the Director-General of WHO addressed the need for cross cutting, multi-sector approaches: 'Policy spheres are no longer distinct. Lines of responsibility are blurred. A policy that makes perfect sense for one sector can have a highly negative impact on others, including health... The lesson is obvious. If policies that serve economic goals want to improve the human condition, they must include health as an explicit policy objective' (WHO 2010). In the same ethos, WHO's *Health in all Policies* approach encourages health to be integrated UN- and government-wide.

Concepts like governance for health move actors from working in separate silos to embracing multidisciplinary approaches. Allowing for specialized input from other sectors can encourage the integration of valuable perspective and expertise, and prevent duplication of efforts or adoption of contradicting policies. A recent example of a successful multisectoral collaboration on an international instrument is the Minamata Convention.

Mercury: the Minamata Convention

Mercury is a naturally occurring element found in air, water, and soil. Exposure to mercury generally occurs through consumption of fish and shellfish that have been contaminated with methyl mercury, though people can also be exposed through inhaling mercury vapours from fossil fuel combustion, industrial processes, and small-scale gold mining operations. Mercury can also be found in electrical and electronic devices, energy efficient fluorescent light bulbs, and batteries. However, at sufficient levels of exposure, mercury can be toxic. Mercury poisoning, to which children are particularly susceptible, can negatively affect the nervous, digestive, and immune systems and, in severe cases, can be fatal.

The continued release of mercury into the environment from human activity, the presence of mercury in the food chain and the demonstrated adverse effects on humans were of such concern that in 2009 governments agreed on the need to develop a global, legally binding instrument on mercury. Environment Ministers at the 2009 session of the United Nations Environmental Protection (UNEP) Governing Council took the decision to launch the negotiations; in 2013, the Minamata Convention, as it was named, was finalized. More than 140 nations negotiated and agreed on the language contained in the Minamata Convention and the document will open for signature in October 2013. The treaty will enter into force once it has been ratified by 50 parties.

Highlights of the Minamata Convention are as follows:

- ♦ Production, export, and import of a range of mercury-containing products will be banned by 2020.

- ◆ Parties are required to develop strategies to reduce the amount of mercury used by small-scale miners.
- ◆ Parties with artisanal and small-scale gold mining operations are required to develop national plans to reduce and, if possible, eliminate the use of mercury in such operations within 3 years of the treaty entering into force.
- ◆ Mercury emissions and releases from various large industrial facilities ranging from coal-fired power stations and industrial boilers to certain kinds of smelters will be controlled.
- ◆ Best available technologies will be used on new power plants and facilities, with plans to be developed to bring emission levels down from current rates.

The results of the UNEP-led negotiations could have been a treaty that addresses only the environmental impact of mercury. However, recognizing that mercury has serious health impact, the negotiating states invited WHO to provide its expertise to inform the development of relevant provisions. WHO provided background materials highlighting where the greatest health gains could be made and provided evidence regarding the use of mercury in medical instruments. The results of the WHO and UNEP joint work can most concretely be seen in the Objectives of the Convention which include clear reference to the protection of the environment *and* human health. Further, Article 16 of the Convention centres on health, encouraging Parties to implement health education and prevention programmes in vulnerable communities and indicating that the Conference of the Parties should consult, collaborate, and promote cooperation and information exchange with WHO, ILO, and other relevant intergovernmental organizations (UNEP 2013). The Minamata Convention, though not a specifically international health instrument, clearly contributes to improving health and, as an international instrument, is an intermediate GPG for health.

International legal paradigms, enforcement, and intermediate global public goods for health

As noted earlier in this chapter, the production of GPGs for health is most effective when states create international legal instruments that contain four essential aspects:

1. The establishment of formal institutions empowered to work on global public health problems.
2. The establishment of procedures through which states and non-state actors can tackle specific global public health problems.
3. The enumeration of substantive duties in connection with particular global public health challenges.
4. The creation of mechanisms to enforce substantive legal duties undertaken by states that have agreed to be bound by international instruments.

The WHO FCTC and the 2005 IHR both integrate all four aspects, as they address institutional, procedural, substantive, and enforcement aspects of the regulation of tobacco products and disease spread, respectively. As binding instruments, these instruments are often called ‘hard law’. However, as demonstrated

by the non-binding Codex Alimentarius and INFOSAN and PIP Framework, which are voluntary, it is not only binding multilateral legal instruments that make up the landscape of intermediate GPGs for health. Those agreements and arrangements that are non-binding, and sometimes identified as ‘soft law’, can play a critical role in establishing the foundations required to produce the ultimate GPG—in this case, health.

The following section provides a brief review of health as a GPG in the context of international law and the spectrum of agreements between nations. The contrasts and similarities between hard and soft international law are presented and the institutional capacity, responsibility, and role of WHO in the creation of intermediate GPGs for health is examined.

Law and non-law: binding and non-binding international instruments and GPGs for health

The ideas and characteristics of soft law and hard law, and their relationship and usefulness, are common themes among international legal scholars and practitioners. With regard to the GPG of health, a very cogent and useful set of articles on this area was presented in the Bulletin of the WHO in December 2002, a special edition focusing on international law and public health (WHO 2002).

As exemplified by the case studies in this chapter, public health concerns are becoming increasingly complex as globalization progresses; so, too then, must and have the international responses been. In overcoming the Westphalian notion of single-nation solutions, ‘the complex network of global health governance structures that are emerging indicates the need for an inclusive approach to engagement with new global health actors’, including civil society, private actors, and public organizations (Taylor 2002; Taylor and Bettcher 2002). It is perhaps reasonable, then, to assert that the first step to producing the GPG of health is to examine the entire spectrum of stakeholders and create processes that are inclusive, to ensure that the intermediate GPG international legal instruments are as effective and efficient as possible.

Among the intermediate GPG legal instruments, traditional legal instruments—namely, treaties—provide the strongest, most effective tools for improving health (Taylor 2002), though they are commensurately difficult to negotiate because they bind parties to discrete, identifiable obligations. Although treaties have variable success in being implemented and enforced, the gestalt created by a negotiation, adoption, and entry into force can be tremendous (Taylor 2002). This certainly was the case for the WHO FCTC process, during which ‘the power of the process’ was often noted as one of the key ingredients to its success.

Perhaps because of the substantial challenges inherent in successfully negotiating a treaty on a topic as multifaceted as health, non-binding instruments have become increasingly utilized as nations seek to reach agreement and move a number of multi-lateral agendas forward (Chopra et al. 2002). Non-binding agreements provide the kind of flexibility that allows nations to act cooperatively and in concert without limiting their own autonomy (Chopra et al. 2002). However, the position and essential

nature of non-binding instruments like resolutions and codes, sometimes called soft law and sometimes called 'non-law', remain unsettled in the rubric of international law (Taylor and Bettcher 2002). In terms of intermediate GPGs for health, non-binding arrangements like the Codex and INFOSAN and the PIP Framework certainly have demonstrated their usefulness, even in the face of not having the more robust implementation and enforcement opportunities that come with traditional international legal instruments.

Global health and GHG is a dynamic, exciting arena with an increasingly complex landscape being painted with each new transboundary health challenge that emerges or is identified. The relationship between hard and soft law has and will continue to adapt to best respond to the needs of global communities, which will in turn look to the WHO FCTC, IHR (2005), the Codex, INFOSAN and the PIP Framework and the Minamata Convention as models of intermediate GPGs on which to build.

WHO and institutional roles and responsibilities in the creation of intermediate GPGs for health

In a review of the nature and usefulness of international instruments for health, it would be remiss not to consider the role of WHO, as the UN specialized agency for health, in the creation of these intermediate GPGs for health. As the institutional umbrella home of four of the five instruments considered in this chapter, it plays a key and central role in fostering and providing a forum for its Member States to create agreements. Notwithstanding this, though, the question of what it can do and what it should do remain topics worth considering.

According to its Constitution, WHO is not simply an institutional home for multilateral health programmes and technical expertise; WHO is vested with substantial normative functions as well, including the Articles 19 and 21 powers to adopt conventions and regulations on matters within its competence (WHO 2007a). Though, with the exception of regulations, these powers are only 'quasi-legislative' in that Member States are not automatically bound to provisions of a given negotiated text, this is nonetheless one of the Organization's most important functions (Burci and Vignes 2004).

By design of its founding Member States, WHO does not, and perhaps should not, have full legislative capacity (Burci and Vignes 2004). It does have substantial comparative advantage, though, in being the primary agent for actualizing international agreements on health. The Organization has the capacity to coordinate its Member States, promote dialogue, and set the global health agenda and provide a platform for negotiations (Taylor 2002), provided it maintains adequate supporting political will and consensus among its constituency (Taylor 2002; Burci and Vignes 2004). WHO is one of, if not the, most potent sources of intermediate GPGs for health.

Conclusion

As intermediate GPGs for health, international legal instruments take on an additional layer of importance in GHG. In providing a robust framework for improving and occasionally even creating health, these instruments are important not only for what they are already doing, but for the potential good new

instruments might be able to deliver. As WHO continues to grow into its normative role, it is likely that additional opportunities to exercise its Constitutional quasi-legislative powers will present themselves. The five examples of intermediate GPGs examined in this chapter, the WHO FCTC, the 2005 IHR, and the Codex and INFOSAN, the PIP Framework and the Minamata Convention, have laid a solid foundation on which WHO and its Member States may build to continue to work toward achieving the GPG of health.

Notes

1. The authors alone are responsible for the views expressed in this publication and they do not necessarily represent the decisions, policy or views of the World Health Organization.
2. The work of the World Health Organizations is carried out by three organs: the World Health Assembly, the Executive Board, and the Secretariat. See chapter IV of the WHO Constitution available at <http://apps.who.int/gb/bd/PDF/bd47/EN/constitution-en.pdf>.
3. A National IHR Focal Point is defined in Article 1 of the Regulations as 'the national centre, designated by each State Party, which shall be accessible at all times with WHO IHR Contact Points'.
4. Defined in Article 1 of the IHR as an 'extraordinary event which is determined (by the WHO Director-General) [...] (i) to constitute a public health risk to other States through the international spread of disease and (ii) to potentially require a coordinated international response'.
5. It should be noted that under Annex 2 of the IHR, States Parties are required to notify WHO of cases of human influenza caused by a new subtype.
6. The WHO Executive Board's main function is to give effect to the decisions and policies of the World Health Assembly (see Article 28 of the WHO Constitution).
7. The document was adopted by the 64th World Health Assembly under Article 23 of the WHO Constitution.

Information systems in support of public health in high-income countries

Tjeerd-Pieter van Staa and Liam Smeeth

Introduction to information systems

Public health sciences have been described by a Wellcome Trust working group as follows: 'effective public health actions are based on scientifically derived information about factors influencing health and disease and about effective interventions to change behaviour at the level of the individual, the family, the community or wider society' (Public Health Sciences Working Group et al. 2004, p. 5). This field of science has made major contributions to the improvement of health such as the effects of sanitary reforms on infant mortality and, more recently, the reductions in cardiovascular disease incidence due to lipid lowering and blood pressure control. However, many challenges remain, such as how to tackle the increased prevalence of obesity and diabetes and how to relate the costs of interventions to their benefits (Public Health Sciences Working Group et al. 2004). This chapter will describe how information systems containing healthcare data can support public health research. We will first describe examples of public health information systems, followed by a description of various developments in these systems, including increased public health use of routinely collected electronic healthcare records (EHRs). More and more clinicians and healthcare professionals are using computers to store information: indeed the 'meaningful use' of electronic health records for patient care has recently been mandated in the United States (Blumenthal et al. 2010). These data sources provide opportunities, among others, to test the effectiveness and impact of public health interventions. We discuss the role of randomization in public health research and conclude this chapter by highlighting the importance of an impact assessment of public health interventions.

Sources of public health information

Vital statistics

Death certificates are routinely collected in many countries in order to report on specific causes of death including, for example, alcohol-related deaths, suicides, and drug-related deaths, deaths involving methicillin-resistant *Staphylococcus aureus* (MRSA) and *Clostridium difficile*, and estimates of excess winter mortality. Trends in, for example, all-age all-cause mortality, deaths from cancer, circulatory diseases, suicide and injury of undetermined

intent, and accidents are reviewed periodically as are the association of mortality rates with socioeconomic deprivation. Live and stillbirth figures are also routinely collected in many countries. The birth counts may be stratified by occurrence within or outside marriage, multiple births, mother's area of residence and country of birth, place of confinement, and father's social class (examples are given at <http://www.statistics.gov.uk>).

Population surveys

Population surveys are frequently used information resources. One example is the US National Health Interview Survey, which targets annually an interview with 40,000 households. Questions include health status and health services utilization and activity limitations due to ill health. The Behavioural Risk Surveillance System is a telephone survey in the US involving 150,000 people. Data are collected on health risks and behaviours, exercise, and diet. The National Health and Nutrition Examination Survey examines diet, nutrition, health behaviours, and risk factors in 5000 randomly selected persons.

A population census provides information about the characteristics of the population and facilitates understanding of the similarities and differences in populations locally, regionally, and nationally. The results are then used to allocate public money for services including healthcare services. They are also used to identify areas with the greatest public health needs. As an example, national census data from the Strasbourg metropolitan area in eastern France were used to develop a small-area index of socioeconomic deprivation. It showed an association between increased rates of myocardial infarction and worse neighbourhood deprivation (Havard et al. 2008).

Disease surveillance

In many countries, there are systems for reporting and notification of cases of certain diseases to the public health authorities. Infectious diseases such as yellow fever and diphtheria are notifiable on diagnosis of a suspected case and should not wait for laboratory confirmation. All notifiable cases are then reviewed and appropriate action may be taken. Analyses of local and national trends are typically published on a regular basis. Despite legal requirements to report certain infectious diseases, reporting rates

for these conditions are not always optimal. To address this, for example, a New York public health institute facilitated public health reporting by creating alerts within EHRs to remind clinicians at the point of care that a particular diagnosis is reportable and providing a link to the reporting form. Patient demographics are automatically populated in the form (Calman et al. 2012).

Administrative databases

There are many administrative databases that contain information recorded for the purposes of managing the healthcare system. Several of these systems can be used for public health research. The Hospital Episode Statistics is a data warehouse containing details of all admissions to National Health Service hospitals in England. It contains clinical information about diagnoses and operations on individual patients, demographic information such as age, gender, and ethnicity, administrative information such as time waited and date of admission, and geographical information on where the patient was treated and the area in which they lived. Main procedures (such as surgical operations) are also recorded. It contains admitted patient care data from 1989 onwards, with more than 12 million new records added each year, and outpatient attendance data from 2003 onwards, with more than 40 million new records added each year (Health and Social Care Information System n.d.).

Registries

A registry is an organized system that uses observational study methods to collect uniform data (clinical and other) to evaluate specified outcomes for a population defined by a particular disease, condition, or exposure. There are many different types of registries. An example of a product registry is the UK national registry of patients on biological therapy: patients starting such therapy are registered and followed, for example, for long-term safety issues. Healthcare service registries include patient-based individual clinical encounters, such as office visits or hospitalizations, and procedures. Examples include registries enrolling patients undergoing a procedure (e.g. carotid endarterectomy, appendectomy, or primary coronary intervention) or admitted to a hospital for a particular diagnosis (e.g. community-acquired pneumonia). These registries may be used to evaluate the processes and outcomes of care for quality measurement purposes. Disease registries use the state of a particular disease or condition as the inclusion criterion. These registries typically enrol the patient at the time of diagnosis at a routine healthcare service. Examples include cancer registries which are widely used for research (Edwards and Bell 2000).

Immunization registries have been created in order to assemble in one site a record of all immunizations and to provide reminder and recall notices when an immunization is due or late. Vaccination schedules are becoming complex due to the number of different vaccinations a child should receive. These may be further complicated by frequent changes of healthcare provider or insurance company. Immunization registries can provide a central repository of all the vaccinations given to children (Linkins 2001).

Electronic health records databases

EHRs are increasingly being used for research and public health purposes. There are currently over 300 EHR databases in

45 countries (http://www.ispor.org/intl_databases). This section describes a few examples of EHR databases that have been widely used for research. The Clinical Practice Research Datalink, previously known as the General Practice Research Database, collates the anonymized EHR information for over 5 million patients currently registered at participating general practices. General Practitioners (GPs) play a key role in the UK healthcare system, as they are responsible for primary healthcare and specialist referrals. If a patient is treated in secondary care or by a specialist, the GP is informed about major clinical outcomes, and long-term treatments are frequently handed back to the GP. Almost all GPs in the UK use computers for maintaining health records, and communications between different health providers are increasingly sent electronically (Williams et al. 2012). The Dutch PHARMO Record Linkage System collects information on patient demographics, drug dispensings, hospital morbidity, clinical laboratory and pathology results, and GP information for more than 3 million community-dwelling inhabitants of 48 geographic areas in the Netherlands (Herings et al. 2012). A recent development in the Netherlands is the Mondriaan project that has developed an IT and governance infrastructure for enrichment and linkage of EHR. Privacy enhancing technology such as linkage through a trusted third party (TTP) is applied and currently data from GPs (one million), community pharmacists (12 million), and various other EHR sources are retrieved for research purposes and as feedback information to healthcare providers (www.projectmondriaan.nl). In Denmark and Sweden, each national healthcare system provides universal coverage to all residents (5.5 million inhabitants in Denmark and 9.2 million inhabitants in Sweden). Healthcare coverage includes visits to GPs, specialists, hospital admissions, and outpatient visits; drug costs are either partially or completely covered. A centralized civil registration system has been in place in each country for many years, allowing for personal identification of each person in the entire population and for the possibility of linkage to all national registries containing civil registration numbers, for example, patient registry, cancer registry, prescription databases, and registry of causes of death (Furu et al. 2010). The Rochester Epidemiology Project medical records-linkage system captures healthcare information for the entire population of Olmsted County in the United States. It includes a dynamic cohort of over half a million patients who received healthcare for any reason. The data available electronically include demographic characteristics, medical diagnostic codes, surgical procedure codes and death information (including causes of death). The system covers residents of all ages and both sexes, regardless of socioeconomic status, ethnicity, or insurance status (St Sauver et al. 2012).

Recent developments in information systems

The electronic information systems in the healthcare system are evolving and increasing (Table 4.1.1). Initial use of electronic healthcare data mostly consisted of aggregate analyses of administrative data such as hospital admission data. When clinicians started to use computers for record keeping, the first research databases collating anonymized EHRs were created. One of the first of these was the VAMP research database that

Table 4.1.1 Stages in the development of EHR databases

Time period (approximate)	Development of EHR databases
1980s onwards	Data collected for administrative purposes (such as hospital admission data and death certificates); mainly used for aggregate analyses
1990s onwards	Clinicians starting to use computers for record keeping (replacing paper records) and data collated into research database. These data initially mainly used for drug safety monitoring
2000s onwards	Monitoring of clinic encounters for symptoms that may represent infectious diseases and other conditions of public health concern
2000s onwards	Linkages between various EHR databases; mainly used to obtain complementary information or to validate outcomes
2010s onwards	Enrichment of routinely collected data by prospective data collection within EHR databases (e.g. collection of blood samples for genetic analyses or patient questionnaires)
2010s onwards	Development and implementation of triage tools to guide clinicians in hospital referral of patients with, e.g. influenza; electronic alerts for eligible patients
2010s onwards	Introduction of randomization at the point of care using the EHR database to identify potentially eligible patients and for follow-up collection of major clinical outcomes (i.e. pragmatic and cluster trials); mainly used to evaluate the effects of medicines in routine clinical practice

started in 1987. This database eventually developed into the Clinical Practice Research Datalink. The richness and completeness of many EHR databases have been increasing over time as more information is being shared electronically between different parts of the healthcare system. Laboratory data provide an example in which test results are increasingly being communicated electronically and loaded automatically into the patient's EHR.

An important development is the increased linkage between different healthcare databases. Typically, linkages are done by a TTP that collects from each data source the patient's identifiers (such as registration number in the healthcare system, patient's date of birth, gender, and postcode) and research numbers. The TTP then matches the records of the various databases retaining the linked records with the various research numbers without any patient identifiers. This approach allows the combination of different healthcare databases. Linkages between different EHR datasets are being done more frequently, benefiting both the quality and completeness of the EHR data. The UK Clinical Practice Research Datalink has been linked individually and anonymously to other healthcare datasets, including the national registry of hospital admissions, the national death certificates (with primary and secondary cause of death), and prospective disease registries,

such as the cancer and cardiovascular disease registries (Williams et al. 2012).

Comparisons of the information in linked EHR databases can highlight incomplete data records and inform efforts to improve data recording in the healthcare system. In a cohort study, primary care records were linked with those from cancer registries in the UK National Cancer Data Repository. Comparison of the two datasets showed a concordance rate of 83.3 per cent, which varied by cancer type. Cancer registries recorded larger numbers of patients with lung, colorectal, and pancreatic cancers, whereas GPs recorded more haematological cancers and melanomas (Boggon et al. 2013).

Anonymized linkages between local air pollution data, records from primary care, hospital admissions and death certificates have been used recently to evaluate the relationships between ambient outdoor air pollution and incident myocardial infarction, stroke, arrhythmia, and heart failure. While evidence was weak for relationships with myocardial infarction, stroke, or arrhythmia, consistent associations between pollutant concentrations and incident cases of heart failure were found (Atkinson et al. 2013).

An example of a public health resource that uses linked healthcare databases is the CALIBER programme. It is linking multiple data sources including the longitudinal primary care data from the Clinical Practice Research Datalink, the national disease registry of acute coronary syndrome, hospitalization and procedure data from hospital admission records, cause-specific mortality from death certificates, and postcode-based social deprivation. Current cohort analyses involve a million people in initially healthy populations and disease registries (Denaxas et al. 2012). A recent study that used this resource was an analysis of the effect of influenza and influenza-like illnesses on triggering acute myocardial infarction (AMI). A self-controlled case series (i.e. only cases were evaluated) identified cases of myocardial infarction from the national registry of acute coronary syndromes and looked for associations with exposure to influenza from the consultation records of GPs. It found that influenza and other acute respiratory infections can act as a trigger for AMI (Warren-Gash et al. 2012).

The Massachusetts Department of Public Health in the United States has developed a system that loads EHRs every 24 hours from clinicians' proprietary software systems. These extracts are organized into separate databases for patient demographics, vital signs, diagnosis codes, test orders and results, medication prescriptions, allergies, social histories, and provider contact details. These data provide clinically detailed surveillance data. Sensitive and specific disease-detection algorithms have been developed to overcome the limited accuracy of code diagnostic data by considering all available data. Diabetes surveillance is done using these algorithms and can provide information on, for example, the frequency of referrals for medical nutrition counselling stratified by race and locality. A comparison of this system and conventional reporting by clinicians showed a significant increase in the quantity and quality of case reports of notifiable conditions (Klompas et al. 2012).

The minimization of risk of preventable harm to patients is a priority for many healthcare organizations. In Scotland, a system has been implemented in routine primary care that provides a rapid audit method of screening electronic patient records to detect patient harm. The objective of this tool is to support clinical improvement efforts (De Wet and Bowie 2011).

The combination of routinely collected EHRs with prospectively collected data is an important development in improving the quality of information resources. An ongoing study in the Clinical Practice Research Datalink is recruiting 6000 persons aged 50–64 year for a survey about working life. Study participants will complete questionnaires about their work and home circumstances and their EHRs will be reviewed anonymously. The inter-relationship between changes in employment (with reasons) and changes in health (e.g. major new illnesses, new treatments, mortality) will be examined. This study will contribute to the evidence-base as to whether working beyond the traditional retirement age is feasible for those with major health problems associated with ageing and the effect of occupational and personal circumstances (e.g. savings, retirement intentions, domestic responsibilities, whether work is arduous or rewarding) (K. Palmer, personal communication 2012).

Syndromic surveillance is the practice of monitoring clinic encounters for symptoms that may represent infectious diseases and other conditions of public health concern. There are several examples in which EHRs are used to conduct this surveillance. An example is QSurveillance which provides weekly information on the consultation rates of flu-like illness in general practices covering a total population of almost 22 million patients (QSurveillance n.d.). A comparable system has been developed in New York State, United States, in which routinely collected EHRs from health centres are transferred daily to the research database. Respiratory illness, fever, diarrhoea, and vomiting are the key symptoms monitored, with analysis to determine when the incidence of these syndromes exceeds expected thresholds (Calman et al. 2012).

Research in EHR databases is now being carried out to refine and validate triage tools to guide clinicians in hospital referral of patients with influenza-like illness during a pandemic. In the first phase of this study (called FLU-CATS), clinicians will record their assessment and management of patients with influenza-like illness. They will be prompted by a pop-up box to provide this information when a diagnosis of influenza-like illness is being entered into the EHR. There will be an automated daily transfer of the anonymized EHRs to the research database (the Clinical Practice Research Datalink). The EHRs will be linked periodically to hospital admission records and data from a regional microbiology network which includes laboratory results on investigations for respiratory pathogens. The collected data will be used to refine and update the triage tools. If the pilot phase is successful, this system could be rolled out to a much larger group of clinics. Such a system is also potentially adaptive, since with ongoing data collection, triage tools can be regularly adapted to changes in virus, human behaviour, and models of healthcare provision in the community (M.G. Semple, personal communication 2012).

Pandemic preparedness is a major public health activity in many countries, including the United Kingdom. The major objectives of the UK strategy are, in case of an influenza pandemic, to identify key clinical, epidemiological, and virological features of the new influenza virus, to count severe cases and identify risk groups affected, to describe the evolving pandemic and its impact at the population level (e.g. by age-group) particularly in relation to hospitalizations and mortality, and to measure the uptake and safety of various pharmaceutical countermeasures. Several information systems would be used to collect the data to be used for this, including primary care consultations, records of calls to

telephone help-lines and web-based advisory services relating to influenza-like illness, virological 'sentinel' surveillance schemes in primary care, laboratory analysis of a sample of cases to identify the genetic features of the virus and analysis of death records (Department of Health 2011).

Future developments in information systems

There is an increasing need to perform studies across different EHR systems and across different countries mainly because of the need for a larger sample size. The healthcare systems in most countries consist of multiple healthcare providers who often use different systems to store data, either on paper or electronically. Furthermore, physicians often record data differently and inconsistently, both on paper and electronically. Various international initiatives are currently ongoing which use different approaches to combine heterogeneous EHR databases. One approach focuses on IT aspects with the aim to develop EHR systems that are interoperable and allow seamless transfer of data (<http://www.transformproject.eu/>; <http://www.ehr4cr.eu/>). All the information in the various databases is mapped together with a detailed understanding of the content of each of the data elements and use of a single coding dictionary across the different databases. An alternative approach is to maintain the EHR data structure as collected by the participating health professionals but to develop a common protocol across the different databases. The operational definitions of how the data are classified will vary by individual EHR database but the research questions will be kept similar. This model is currently used by the Innovative Medicines Initiative PROTECT project (<http://www.imi-protect.eu/>). The third approach is used by the OMOP initiative in the USA: all EHR data from the different databases are integrated into a central research database according to a common data model (<http://omop.fnih.org/>). A distributed network model where basic analyses are run on federated datasets generating common input data and subsequent local aggregation and central pooling of results, constitutes the fourth approach to dealing with heterogeneous EHR databases. The EU-ADR project uses this approach. In one of their studies, data from eight European healthcare databases (administrative claims, medical records) were combined. This dataset included over 1.9 million individuals (59,594,132 person-years follow-up) who used 2289 different drugs. It found for a frequent event such as AMI, there were 531 drugs (23 per cent of total) for which an association with relative risk ≥ 2 , if present, can be investigated. For a rare event such as rhabdomyolysis, there are 19 drugs (1 per cent) for which an association of same magnitude can be investigated. It concluded that even larger databases would be required to detect signals for less frequent exposures and outcomes (Coloma et al. 2012).

A recent development is the use of EHRs to measure the quality of clinical care and provide financial incentives through 'pay-for-performance' programmes (Campbell et al. 2009). EHRs are used to evaluate clinician and system performance with the goal of making healthcare safer and more efficient. The adoption of computerized clinical records itself may be associated with improved care and outcomes (Cebul et al. 2011) although some doubts remain (Classen and Bates 2011). There are several different dimensions in which quality of healthcare can be measured.

Examples of different quality measures include the number of patients with diabetes seeing an ophthalmologist, clinical outcomes in patients with hypertension, percentage of clinicians reviewing out-of-range laboratory results with a certain number of hours, and the percentage of patients receiving incorrect medications (Weiner et al. 2012). The quality and completeness of the EHRs are of course critical in achieving the goals of the 'pay-for-performance' programmes.

Internet postings, blogs, and social media postings may provide another source of information for the early detection of new infectious disease epidemics. A recent study analysed the queries to online search engines, which are used by millions of people around the world each day. It concluded that this approach accurately estimated the level of weekly influenza activity in each region of the United States, with a reporting lag of about 1 day. The use of search queries could detect influenza epidemics in areas with a large population of web search users (Ginsberg et al. 2009). This potential use of Internet searches was tested in a US study that compared Internet searches with rates of outpatient visits for influenza-like illness and of confirmed laboratory tests. It was found that Internet searches were highly correlated with rates of outpatient visits for influenza-like illness but less correlated with rates of laboratory-confirmed influenza (Ortiz et al. 2011). The main limitation of these analyses of unstructured Internet data is that it may be difficult to separate activities by concerned healthy people from those with the disease of interest. Healthcare seeking behaviour, physician testing practices, and Internet search behaviour can be influenced by high levels of media coverage (Ortiz et al. 2011).

The information on the Internet can also be evaluated for the monitoring of side effects of medicines. A study evaluated the text on Internet message boards dedicated to drug abuse in order to compare different prescription opioids. Over 48,000 posts were analysed and the unstructured text was coded. It was found that the number of posts on these drug abuse message boards varied between the different opioids (Butler et al. 2007). While this approach is interesting, one cannot conclude that these differences in drug abuse messages were caused by the pharmacological differences between the opioids. Different levels of information provision by, for example, the clinicians or in the information sheet or prescribing to different patient populations could also lead to different levels of Internet activities.

Randomization in public health research

The present allocation of healthcare interventions is often inconsistent. Clinicians will be influenced in their prescribing behaviour, not only by clinical considerations, but also by other issues including drug preferences, exposure to marketing materials, and guidance from the local healthcare funders, which will vary considerably between practices and clinicians (Adamson et al. 2012). Clinicians will respond differently to uncertainties in the evidence base. The prescribing of antibiotics to patients with mild to moderate exacerbations of chronic obstructive pulmonary disease provides an example of this. A review of EHRs found major differences in the rate of antibiotics prescribing to these patients. Very few patients received an antibiotic in some clinics while antibiotics were routinely prescribed in other clinics. This variability in care (due to a lack of randomized trials conducted in these patient

groups) produces a potentially unfair lottery for the receipt of healthcare interventions. Treating patients in this inconsistent manner generates no new evidence to improve clinical practice. On the other hand, randomization with structured data collection would provide the evidence to guide clinicians in selecting treatments. A possible model would be to offer randomization to all willing patients as part of routine clinical care in every situation where there is genuine uncertainty about which of two or more widely accepted treatments is best. The EHRs could be used to measure major clinical outcome and follow progress (van Staa et al. 2012). An analysis of the trial evidence for medicines used by millions of patients and with blockbuster sales showed that only one of the 24 top blockbusters in 2011 had a randomized trial including more than 10,000 participants and only few of the blockbusters had evidence of beneficial effects on mortality (Ioannidis 2013). A mega-trial with mortality as an outcome could address concerns about side effects and also provide evidence of effectiveness of medicines in routine clinical practice.

EHR databases could offer an ideal platform to undertake large pragmatic trials, with randomization at the point of care and collection of follow-up data using the EHR (van Staa et al. 2012). Such an approach would allow the assessment of effectiveness of healthcare interventions in everyday clinical practice among representative populations. An example of an ongoing study is the RETROPRO trial, in which patients with high cardiovascular risk are randomized between simvastatin and atorvastatin (van Staa et al. 2012). After confirmation of trial eligibility by the patient's clinician and after informed consent, a patient is then randomized between simvastatin and atorvastatin. Heart attacks are measured using the routinely collected data from primary care, linked data from hospital admissions, from a prospective disease registry, and from death certificates. The patient's clinician can also be asked to confirm and validate the occurrence of a heart attack. The outcome of death can be measured using the primary care data and linked death certificates; this outcome is generally well recorded as the payments to primary care clinics will depend on the number of live patients and notification of death certificates is well established. Discontinuation and non-compliance with statin treatment over time is also an important outcome measurement in this pragmatic trial. For example, if patients preferentially use atorvastatin for a longer period of time, this could mean a substantially lower number of patients suffering a heart attack. In most trials, study participants are regularly monitored and instructed how to take their medicines. But the rates of persistence are often considerably lower in routine clinical practice, as stringent monitoring procedures do not apply. Pragmatic trials that collect follow-up information unobtrusively (e.g. from EHR databases) would provide the answers that decision makers need: that is, will this intervention make a difference in routine clinical practice compared to alternative strategies (Tunis et al. 2003).

Cluster trials randomly allocate entire areas or health service organizational units to intervention or control groups, with outcomes evaluated for individuals within each cluster. They facilitate pragmatic evaluation of the effectiveness of interventions delivered in routine practice settings. Public health interventions could be tested in cluster trials as one can, for example, implement the novel intervention in one set of randomly selected clinics and the old intervention in the remaining clinics. The effectiveness of screening programmes could also be tested in cluster trials, with

half of the clinics conducting the screening and the other half not. An example of a study that used EHR data is a study that tested the effectiveness of providing clinicians with the guideline recommendations on antibiotic prescribing in respiratory illness. Electronic prompts are activated during a patient's consultation for upper respiratory illness. The EHRs are used to measure the outcomes of interest, which include the rate of antibiotic prescribing (Gulliford et al. 2011).

Phased access to new interventions has been proposed as a method to measure effectiveness and safety. Practices or regions would be randomized to early or late access and the EHR data would be used to measure the outcomes of interest. Because practices are randomly chosen for each new intervention, a practice will have access to some of the new interventions (Adamson et al. 2012).

Impact assessment of public health interventions

The measurement of outcomes of public health interventions in routine clinical practice should be considered a major public health activity. This impact assessment can inform the extent of uptake but also identify any issues with the implementation of the public health activity. However, this impact assessment is not consistently done. For example, measurements of outcomes are lacking in a major UK programme that targeted the use of statins in patients with high cardiovascular risk. Following a detailed review of evidence, the UK National Health Service introduced a population-wide vascular risk assessment programme. This consists of a systematic approach to assessing risk of vascular diseases for everyone between 40 and 74 years who is not yet diagnosed with cardiovascular disease or treated for risk factors. Statin treatment should be initiated if a patient has a high risk (20 per cent or greater 10-year risk) of cardiovascular disease (National Health Service Health Check Programme 2008). However, a recent analysis of the EHRs found that many healthy patients were prescribed a statin despite having a below-threshold cardiovascular risk and that there was wide variation between practices in the extent of statin prescribing to patients at high risk.

Another example of the difference between intended use according to guidelines and actual use in clinical practice concerns the selective cyclooxygenase-2 inhibitors (coxibs). These drugs ranked, before September 2004, among the most commonly used medications in the world. They were developed to minimize the upper gastrointestinal side effects of conventional non-steroidal anti-inflammatory drugs. A large number of cost-effectiveness analyses were conducted in order to provide clinicians with guidance on which patient groups should be treated with coxibs. These analyses were based on mathematical models that took into account the higher prescription costs and lower incidence of gastrointestinal side effects of coxibs. The assumptions that were used in these models were obtained from the main coxibs randomized trials. However, an analysis of EHRs found that the vast majority of coxib users in routine clinical practice would not have been eligible for the main coxibs randomized trials, as they did not have osteoarthritis or rheumatoid arthritis and only used coxibs intermittently or short term. Thus, the many cost-effectiveness analyses that were conducted for coxibs lacked external validity and were of limited value in guiding clinicians on how to treat

patients in routine clinical practice. The authors of the EHR analyses concluded that the field of health technology assessments should move from evaluating *cost-efficacy* in ideal (hypothetical) populations with ideal interventions, to *cost-effectiveness* in real populations with pragmatic interventions (van Staa et al. 2009). The clinicians were not provided with any guidance on how to use coxibs in the vast majority of patients who could be treated with coxibs. Public health interventions should be developed with a focus on who could be targeted in routine clinical practice rather than on who had been included into randomized trials. It has been proposed that public health programmes should be preceded by a systematic review of the research evidence assessing the likely effects of these programmes followed by an impact evaluation after launch (Oxman et al. 2010).

Scientific challenges in research with electronic healthcare data

Data quality is of course very important for research that uses EHR data. There are several dimensions of data quality. The accuracy and validity of the information in EHR databases will depend on the level and specificity of the coding of medical data at the clinics. A clinic that mostly records data using unstructured free-text or using non-specific codes will provide data that are less useful for research. Data quality also depends on the completeness of information. A clinic that is not routinely informed about, for example, hospitalizations of their patients will not provide complete data, even if the clinic codes the medical data to highest standards. Reliability of information includes the level of changes in data collection over time. As an example of secular changes, the Quality and Outcomes Framework introduced in England in 2004 resulted in a substantive increase of the data included in this framework. Relevance of the collected data for the desired use is another component of data quality. An EHR database that is based on records from GPs may not contain all the data considered relevant by a specialist for making a diagnosis. Timeliness of information processing is also critical for data quality (Audit Commission 2007). Studies that use EHR data for public health research will need to consider these different aspects of data quality.

There are many different EHR systems and similar information may be recorded and stored differently, making it difficult to extract information in a standardized manner or to share information between different partners. Complex systems may need to be built in order to make computer systems interoperable and to exchange EHR data with public health agencies. An example of such a system is the US National Electronic Disease Surveillance System. This is a web-based infrastructure for public health surveillance data exchange between the Centers of Disease Control and the 50 US states. Forty-seven states had in 2010 fully operational general communicable disease electronic surveillance systems, of which 39 states had systems that were interoperable and 42 states had the capacity to receive electronic laboratory reports (Centers for Disease Control and Prevention 2011).

Ethical aspects of research with electronic healthcare data

Healthcare data contain sensitive information about individuals. Adequate protection of individuals' privacy and data security are

very important requirements for researchers to adhere to. EHR databases typically remove patients' identifiers (such as name, address, and postcode) from the research database. In some databases, researchers will never be able to contact the clinician or patient; these data are considered fully anonymized. In other databases, researchers will not know the patients' identifiers but they are able to contact the clinician or patients through a gatekeeper; these data are considered pseudo-anonymized. In the Clinical Practice Research Datalink, the patient's clinician can be contacted (following approval by an ethics committee), who can then review the request and contact the patient, if appropriate.

There is considerable debate about whether (pseudo)anonymized healthcare data should be made available for research. In an opt-in system, data can only be made available to researchers dependent on their informed consent. In an opt-out system, patients can refuse to have their data used for research. In other systems, anonymized data are considered exempt from consent or dissent requirements and can be used for research as long as the data do not contain patient identifiers. A recent discussion in the European parliament proposed that 'processing of sensitive data for historical, statistical and scientific research purposes is not as urgent or compelling as public health or social protection.' Identifiable health data about an individual could never be used without their consent (such as cancer registries). Pseudo-anonymized data could be used without consent, but only in cases of 'exceptionally high public interest' such as bioterrorism (European Parliament 2012). At the time of this writing, the discussions around European data privacy regulations are still ongoing.

The critical question is whether the right of data privacy trumps all other rights and duties or whether there is a balance between different considerations. There is the right of patients to receive proper treatments and the duty of the healthcare to, for example, monitor treatments for effectiveness and safety and be cost-effective. A healthcare system that generates and applies the best evidence for collaborative healthcare choices of each patient and provider has been defined as a learning healthcare system (McGinnis 2010). Such a system would continuously test interventions and collect data on the outcomes and then use the results to inform and improve clinical practice. Scientific research including public health requires high-quality data, and a learning healthcare system that aims to continuously improve cannot be achieved without such data. It has been proposed that data governance should be viewed as a matter of weighing up the value accruing to individuals, such as privacy and consent, against the value that the research may generate for the public (Rumbold et al. 2011).

The discussion about rights of data privacy and the research use of EHRs should not be restricted to abstract legal notions but also consider the likelihood of data privacy breaches and how these can be minimized. Staff training and standard procedures are essential, but the skills and attitudes of staff are also very important to ensure that data are treated with appropriate care. Regular audits of data security by external experts can also help to maintain a culture of continuous improvement (MacKenzie et al. 2011). With appropriate data security procedures, the risk of breaches of data privacy could be minimized. Also, the standards and quality of research are important considerations in the balancing of rights of data privacy and the research use of EHRs. Registration of the study prior to the start of the analyses and external access to protocols after completion of the analyses have been advocated

strongly for randomized trials (Chan et al. 2006). External access to protocols and the possibility for independent researchers to replicate the study findings could help to improve research standards. A public health system that uses EHRs for high-quality and transparent research and with minimal risk of privacy breaches is clearly ethically superior to a system that applies few standards.

Conclusion

Information systems are critical for public health activities with information being exchanged between public health agencies, clinicians/healthcare providers, individuals, and communities. The EHRs can provide information on diseases and healthcare activities and electronic alerts within the EHRs can be used to remind clinicians of necessary or required public health activities. The effectiveness of some public health interventions can be monitored and also tested using the EHRs. Better data on risks and benefits of healthcare interventions can also help to improve decision-making and informed consent by individuals (Calman et al. 2012). The increasing computerization of the healthcare system will offer many important opportunities to improve public health activities.

Information systems and community diagnosis in low- and middle-income countries

Peter Cherutich and Ruth Nduati

Introduction to information systems and community diagnosis in low- and middle-income countries

Individuals, local communities, governments, and national and international bodies are heavily investing in health as a key pillar for development. The International Covenant on Economic, Social and Cultural rights of the United Nations Assembly of 1966 and the WHO Constitution affirm that all human beings have inalienable rights that include ‘the enjoyment of the highest attainable standard of health’ (UN General Assembly 1966). And in Ottawa in 1998, the World Medical Association declared that ‘children need to grow up in a place where they can thrive—spiritually, emotionally, mentally, physically and intellectually’ (World Medical Association 1998) with access to health services when needed. The global community has further shaped the global health landscape over the last few decades through political declarations, research, and increased funding. The Declaration of Alma Ata, Health for All by the year 2000, the UN charter on human rights, the Abuja Declaration, and the G8 summits have created a momentum for global health. Health is therefore part of a global social and human rights imperative. The overarching international global health aspirations are captured in the commitments made to achieve the Millennium Development Goals (MDGs) (UN General Assembly 2000) by the year 2015.

Three of these MDGs—4, 5, and 6—are directly health related while the others have an indirect but nevertheless significant effect on health and quality of life. Each of the MDGs has a defined set of targets whose attainment has galvanized the international community. Following these declarations of commitment to the promotion of health globally, significant resources have been made available through the President’s Emergency Plan for AIDS Relief (PEPFAR), the GAVI Alliance, The Bill and Melinda Gates Foundation, The Global Fund for AIDS, TB and Malaria, and others to support these objectives. Countries and communities are obligated to ensure these resources are utilized accountably in terms of outcomes and impact and information systems and community diagnosis are tools for evaluating accountability.

One major drawback to the attainment of the MDGs is that many MDG-related health indicators cannot attract major international

attention or investments and that in low- and middle-income countries data availability on these indicators is limited (Murray 2007). Monitoring the flow of resources as well as the potential impact of those resources on health outcomes especially in low- and middle-income countries where the burden of disease is high constitute a major goal of community diagnosis.

Overview of community diagnosis

Community diagnosis is a composite mechanism that informs priorities and tracks the progress of health metrics. Community diagnosis, in contrast with clinical diagnosis which is a patient–clinician interaction, refers to the identification and quantification of health problems at the population level. Information systems and community diagnosis in low- and middle-income countries fundamentally builds on the core of epidemiological surveillance and includes the following:

1. Systems to monitor magnitude and temporal trends of disease/health.
2. Identifying risk factors driving continued trends.
3. Targeting/prioritizing interventions or planning services and/or rationing limited resources (human and financial) for maximum impact.
4. Assessing impact of intervention on desired outcome.

The World Health Organization (WHO) defines community diagnosis as a quantitative and qualitative description of the health of citizens and the factors which influence their health including the population’s perception of their own health. It identifies problems, proposes areas for improvement, and stimulates action. Community diagnosis provides data reference for the region and provides an overall picture of the local community and the residents’ concerns.

For the purposes of public health, a community is defined as a cluster of people with at least one common characteristic (geographic location, occupation, ethnicity, housing condition, exposure to similar risk factor, etc.). For example, mine workers constitute a community since their occupation exposes them to high risk for HIV transmission and acquisition as well as other occupational hazards (respiratory illnesses, injury, etc.).

Process of community diagnosis

There are four steps in carrying out a community diagnosis:

Initiation of a community diagnosis: a community diagnosis begins with the determination of the scope of areas to be studied. The study may include health status, lifestyles, living conditions, socioeconomic conditions, physical and social infrastructure, inequalities, as well as public health services and policies. The scope of the community diagnosis depends on the client, the purpose and the resources that are available for the exercise.

Data collection: tools for community diagnosis include primary and secondary data collection techniques. The primary data collecting techniques include key informant interviews, mapping, questionnaires, observations, focus group discussions, anthropometric surveys, and participatory rapid appraisals. Secondary data collection techniques generally involve review of records.

A community diagnosis should be well designed to ensure adequate representation of different members of the community. Typically, community diagnosis is cross-sectional but repeated measurements enable determination of trends in the population and may be used to monitor the impact of an intervention.

Data analysis: the raw data then needs to be organized and statistical tests and inferences made. The statistical information is best presented as rates or ratios such as mortality and morbidity rates which can be further analysed to determine their correlates for the purpose of defining those at risk or those in need of healthcare. Trends and projections are useful for monitoring changes over a time period for future planning, for example, mortality trends as presented in demographic health surveys or monitoring of the progress on the implementation of health interventions as well as community perceptions regarding health. Local district data can be compared with other districts or the whole population and help identify the priority areas of hot spots for immediate intervention.

Diagnosis: the diagnosis of the community is based on evaluation of the analysed data. Ideally the community diagnosis should be arranged around the following themes:

- ◆ Health status of the community—measures of disease occurrence are used to describe the status of health of the community such as incidence and prevalence.
- ◆ Determinants of health in the community—measures of disease association such as odds ratios, population attributable risks.
- ◆ Potential for health interventions.

Community engagement

Community diagnosis is a dynamic process. Applying the methods of community diagnosis requires meticulous planning and community mobilization. Large-scale household surveys like the Demographic and Health Surveys (DHS) and community-based studies (Joint United Nations Programme on HIV/AIDS 2011) typically involve the community in the planning, implementation, and feedback. The opportunity cost of not engaging survey participants and the relevant communities is very high since surveys are expensive. In order to achieve high participation rates, community leaders and other opinion shapers may aid in convincing reluctant survey participants and dispel myths, especially around blood draws. A further example is in the conduct of verbal autopsies. To achieve a balance between recall bias and sensitivities around grieving, administrators of verbal autopsy require skill to

interact with the community but also to ensure that they engage respondent families after a reasonable duration (usually 3 weeks) following the death of a member.

Key steps of community entry are outlined as follows:

- ◆ Set up a coordinating committee at national and regional level. Designate one of the subcommittees to spearhead community engagement:
 - Provide advance notice to the local community about the survey.
 - Identify regional or local coordinators of the survey.
- ◆ Develop key messages with details of the goal, the process, and outcome of the survey.
- ◆ Map out key community leaders and identify local structures for engagement:
 - Identify community needs through structured process.
 - Identify community champions.
 - Align community expectations (e.g. for recruitment as survey personnel) with survey realities and possibilities.
- ◆ Sensitize the media and launch media campaign if necessary.
- ◆ High-profile launch of survey by key political leaders may be appropriate in some settings.
- ◆ Regular feedback on the progress of survey—clarify any misconceptions that may continue to arise.
- ◆ Final feedback on the findings of the survey and return of any biomarker results if appropriate.

Community involvement further assures that the knowledge derived from any domain of community diagnosis can be repackaged in a manner relevant to the beneficiaries (Madhavan et al. 2007). Health programme managers and policymakers should also make sure that they consult with frontline healthcare workers before they introduce any new health information system. A comprehensive review of existing solutions must be done before decisions on high-technology investments are made (Detels et al. 2005). Failure to do this will result in resentment and rejection of the new system.

There are numerous examples of questions that are well addressed by conducting a community diagnosis. Are trends in mortality and nutritional status moving in the right direction? Is the country on track to achieve the health MDGs? How high is coverage for each intervention? Are trends moving in the right direction towards universal coverage? Are there gaps in coverage for specific interventions? How equitable is coverage? Are certain interventions particularly inaccessible for the poorest segment of the population?

Community diagnosis and information systems are useful in determining the Global Burden of Disease (GBD) (Murray et al. 2011), populations at risk, generating denominators for coverage, unit costs, etc. The data generated from community diagnosis may inform mathematical modelling aimed at prioritizing interventions with the highest public health impact (Hallett et al. 2008; Njeuhmeli et al. 2011).

Community diagnosis, if appropriately done and well disseminated, has the potential to:

- ◆ Improve national and subnational delivery of health services through properly costed national health plans that emphasize

service integration and include programmes for reproductive, maternal, newborn, and child health.

- ◆ Strengthen health information systems, including vital registration systems and national health accounts, so that timely, accurate data can inform policies and programmes.
- ◆ Increase domestic funding allocations for and expenditures on health.
- ◆ Build the numbers, motivation, and skill mix of the health workforce.
- ◆ Analyse subnational data to identify gaps and inequities and to monitor and evaluate programmes and policies.
- ◆ Develop strategies to reduce the burden of disease and improve efficiency of health programmes.

Priority health metrics for community diagnosis in low- and middle-income countries

Depending on specific health priorities of countries, the burden of disease and risk factor profile, the data required may include demographic characteristics, educational infrastructure (schools) and educational attainment, waste disposal, housing conditions, vector control, nutritional status of the population, and the social environment, etc. (MacQueen et al. 2011).

Outlined in the following sections are the key health metrics relevant to low- and middle-income countries, and which are of interest to the global health community.

Demographic: life expectancy at birth

The number of years that a person born today (or at any other designated point in time) is expected to live, given the mortality patterns for the country in which he or she lives at the time of birth. This metric is modelled based on the age-specific death rates obtained from a combination of sources including vital registration systems and household surveys and censuses. Advances in public health and improvement in quality of life are accompanied by increased life expectancy.

Mortality

The vital events necessary for measurement of mortality are live births, deaths, and still births. A complete vital registration (VR) is the best source of mortality data. However, most low- and many middle-income countries have incomplete VR systems, especially data pertaining to perinatal deaths (stillbirth and early neonatal deaths) and therefore information collected through this system is often non-representative. In settings where VR is incomplete, reliance on interviews from relatives to ascertain probable cause of death is essential. This is called verbal autopsy (VA). The mortality questions frequently asked include household deaths in the last 12 months, and about parental, spousal, and sibling survival (Gakidou et al. 2004). Although these surveys are subject to recall bias, they nevertheless provide a robust source of mortality data for resource limited settings.

Maternal mortality ratio

Maternal death is defined as the death of a woman as a result of pregnancy or childbirth, during pregnancy, or within 42 days

after delivery. Classification of a death as a maternal death is highly dependent on a recorded diagnosis or the conduct of a VA to ascertain the cause of death. Pregnancy-related deaths in early gestation may be under-reported. Secrecy and stigma surrounding pregnancy may also impede reporting of a maternal death. Standardized interview tools to document maternal deaths to be used during surveys have been developed. The maternal mortality ratio (MMR) is expressed as the number of maternal deaths per 100,000 live births over a specified period.

Child mortality

Age-specific mortality rates are categorized and defined as follows:

- ◆ Neonatal mortality: the probability of dying within the 1st month of life.
- ◆ Post-neonatal mortality: the difference between infant and neonatal mortality.
- ◆ Infant mortality: the probability of dying before the first birthday.
- ◆ Child mortality: the probability of dying between the first and fifth birthday (the sum of the probabilities of dying in the 2nd, 3rd, 4th, and 5th years of life).
- ◆ Under-5 mortality: the probability of dying between birth and the 5th birthday.

All rates are expressed per 1000 live births, except for child mortality, which is expressed per 1000 children surviving to 12 months of age. The other important measure is perinatal death rate which is total stillbirths plus 1st-week deaths as a ratio of the total live births.

Calculation of the probability of dying for each year of life usually relies on data from a survey or registry of all birth and death histories. When such data are not available, child mortality would be estimated for any given calendar year by summing all reported deaths of children 1–4 years of age that occurred in a given year and dividing that number by the number of live births in the same year or the estimated number of children aged 1–4 years. When VR is incomplete, periodic surveys (Demographic Surveys and Census) data is used to determine the estimates of infant and child mortality.

Cause of death

VR is the gold standard for obtaining cause of death information. The quality of information collected determines the extent to which deaths can be attributed to different causes. The ICD-10 provides standard disease classification although its utility in the context of community diagnosis is diminished by incomplete medical records and failure of the clinician to commit to a specific diagnosis. VA is increasingly being used to supplement incomplete VR systems. Abbreviated verbal autopsies have also been used in refugee camps and in emergency situations. Accuracy of the verbal autopsies requires careful development of the case definition to be used in the survey. Community members may use medical jargon with a completely different meaning from the health worker and therefore formative research is required to anchor the VA in the local context (Irimu et al. 2008). VA reports are used to trigger important health action. For example, a recorded increase in mortality from measles should trigger a vaccination campaign in the affected area.

Morbidity

Morbidity estimates the relative prevalence (new and old cases) of a particular disease. In developing countries, most morbidity data is obtained from hospital records. Health facility data is almost always available in low-resource settings. Aside from the fact that these data are rarely collated and disseminated, health facility records including hospital discharge records are frequently biased since it is usually the most severe cases that are admitted to hospital. Additionally, those who are poorer and live further from health facilities are unlikely to utilize them. One innovative way of obtaining morbidity data is through demographic surveillance systems (DSSs), which are typically community-based systems in defined geographical areas that integrate regular household surveys and health examinations.

Composite measures of death and morbidity

The disability-adjusted life year (DALY) combines years of life lost (YLL) due to premature mortality and time spent with reduced health that is years lived with disability (YLD) into one measure. This is the metric employed by WHO to estimate the global burden of disease. The GBD 2010 shows a decrease in DALYs by 23 per cent in the period 1990–2010 with contribution of deaths by children aged less than 5 years declining from 41 per cent in 1990 to 25 per cent in 2010 (Murray et al. 2012). However, estimation of DALYs is not without controversy although recent iteration of DALY estimations is more robust (Box 4.2.1). Additionally the GBD 2010 highlighted significant disparities in burden of disease across countries and within regions (Fig. 4.2.1). Low- and middle-income countries should utilize the information available through the GBD for priority setting and allocation of resources.

Risk factors

The determination of risk factors for major health outcomes is vital if countries are to improve health outcomes. The assessment of population exposure of these risk factors through surveys has been widely used (Ministry of Health, Kenya 2007; Cherutich et al. 2012). When applied correctly, surveys produce valid trend data and can be used to plan interventions and project future health needs. Health examination surveys are rarer and more expensive. National censuses, although appropriate, are less often used to elicit risk factor assessment mainly because of the tremendous cost that would be involved. Cross-sectional surveys are not able to explain causal relationships since exposure (risk) and outcome are measured at the same time.

Functional health status

Functional health status of communities is important so that prevention of harm and improvement of quality of life can be prioritized (Institute of Health Metrics and Evaluation 2009). Information regarding vision, hearing, cognition, and pain can be collected through community surveys although in many developing countries it can be expensive. However, simpler tools such as MOS short form 36 (SF-36) (<http://www.sf-36.org>) and the Euroquol EQ-5D (<http://www.euroquol.org>) are available and can be utilized in low-resource settings to capture self-reported critical information on physical functioning, mental/emotional function, pain, mobility, cognition, etc.

Box 4.2.1 Case study: the Global Burden of Disease

Disability-adjusted life years (DALYs) account for both premature mortality and time spent with reduced health, that is years lived with disability (YLDs) whether short or long term. In order to determine the impact of disease or injury at population level there is a need to have valid measurements of health which are replicable across different populations. Furthermore, there is a need to determine the severity of one outcome relative to the other and therefore a weighting system—disability weight was used where 0 = minimal or no disability and 1 = severe disability equivalent to death.

Since the GBD work was published in 1990 there has been debate on the validity of the disability weights used in the original study especially since these weights were now being used on a much wider scale and in different settings. The discussions have revolved around: (1) how do you define the construct being measured, (2) what methods should be used to measure the construct to elicit responses from individuals or groups, (3) whose responses should be elicited, and (4) how universal are the resulting weights?

The GBD 2010 study teams have conducted a multi-country study to validate the disability weights (Murray 2012). The consensus was that the construct would be health outcome and not welfare outcome since the latter varies considerably with the social and environmental context. Method of trade-offs was used with a series of paired questions associated with the 220 unique health outcomes that described the non-fatal outcomes of the GBD study. The comparisons were based on a lay description of each of the conditions that emphasized the major functional symptoms associated with each health state using non-clinical vocabulary. The responses from the general public were adopted in formulating disability weights unlike the past where disability weights were derived from the judgements of a small group of health professionals. Individuals with the various conditions were not interviewed since this would introduce an adaptation bias. Finally to address the question of their applicability in different global locations, the study was carried out in five countries: the United States, Bangladesh, Indonesia, Peru, and Tanzania. At household level an individual aged 18 years or more was randomly selected to respond to the questions. Within these countries rural and urban populations were surveyed across different socioeconomic strata. In addition, an open-access web-based survey was carried out. The study demonstrated that disability assessments are consistent across diverse populations and different cultural environments. There was a pattern of agreement in the disability weights derived in this 2010 study compared to the 1990 study; however, in the mild range, many disabilities had lower weights.

The refinement of these disability weights means that countries can use data from the GBD to plan healthcare or even in the clinical setting improve communication regarding long-term outcomes. The study also illustrates the importance of collaboration between public health departments and research institutes/universities. The authors of this paper rightfully highlight the need to do further work to refine the lay description of the health outcomes of the different conditions.

Health expenditure per capita

Healthcare providers, managers, and policymakers are accountable to communities, governments, and donors for the utilization of financial resources. Conversely donors and governments require financial information in order to allocate resources more equitably and efficiently. Many developing countries have now set up systems to produce National Health Accounts (<http://www.who.int>; <http://www.phrplus.org/Pubs/prim1.pdf>). National Health Accounts (NHA) is an internationally accepted tool for summarizing, describing, and analysing the financing of national health systems. The NHA is derived from data on disbursements, budgetary allocations, and expenditures by different entities within the healthcare system. In order to inform the NHA, household surveys as well as facility surveys are used. Household surveys among others, provide information on the balance of payments between out-of-pocket and institutional expenditures. Health facility surveys provide information on the costs of services to both the user and supplier and these surveys may include inventory recording, equipment audit, infrastructure assessments, etc.

Human resource inputs

Human resources data in terms of numbers, geographical distribution, type and level of skills, as well as repartition across the public and private sectors, is rarely available. The International Health Facility Assessment Network (IHFAN) supported by USAID and MEASURE Evaluation is one such mechanism for obtaining relevant data in the health workforce in developing countries. With slight modifications, countries can integrate these measurements into the country health information system. Key aspects for this metric include training, specialty or cadre, education levels, skills, and whether they work in the private or public settings.

Effective coverage

Effective coverage measures the proportion of health gain realized through delivering quality interventions (Shengelia et al. 2005). To calculate effective coverage, one requires information on the population in need, the utilization of the particular intervention, and the quality of the delivery of the intervention. Surveys provide the best information regarding the burden of disease in a community and the denominator population. Utilization rates can be collected from health facilities and community surveys. For example, effective coverage for childhood immunization is defined as children having received BCG (Bacille Calmette–Guérin), three doses of DPT+P (diphtheria, pertussis, tetanus, and polio) vaccines, and measles vaccine by 12 months of age.

Cost-effectiveness

Cost-effectiveness analysis (CEA) is a tool that is used to compare the cost of a health intervention with the expected health gains. To impute CEA several pieces of information are required including costs of inputs (such as human resources, medical supplies, etc.) and outputs (such as number of caesarean sections done). NHA, where available, and health facility surveys are important sources of information for input and output data. Using the CEA approach it is possible to identify a minimum package of interventions that may impact a certain health outcome, for example, neonatal survival (Darmstadt et al. 2005).

Measurement strategies for key health metrics

Disease-specific indicators of global health importance have been integrated into information systems of many countries. However, as outlined in Table 4.2.1, some of these indicators are minimally

Table 4.2.1 Measurement of selected indicators for the Millennium Development Goals

Indicator	Type of indicator	Public health importance	Measurement strategy
4. Prevalence of underweight children under 5 years of age	Risk factor	High	Household surveys with anthropometric measurements with some inconsistency across age groups measured
4a. Children under 5 moderately or severely underweight, percentage			
4b. Children under 5 severely underweight, percentage	Risk factor	Adds little value to 4a	Household surveys with anthropometric measurements with some inconsistency across age groups measured
5. Proportion of population below minimum level of dietary energy consumption.	Risk factor	Low, adds little value to prevalence of underweight	Details not available
5a. Undernourished as a percentage of total population			
5b. Undernourished, number of people	Risk factor	Low, same information content as 5a	Details not available
13. Under-5 mortality rate	Health outcome	High	Vital registration in countries with completer systems, complete with birth histories, or children ever born and children surviving questions on household surveys
14. Infant mortality rate	Health outcome	Low; redundant, correlation coefficient with under-5 mortality rate in 0.99	Vital registration in countries with completer systems, complete with birth histories, or children ever born and children surviving questions on household surveys
15. Proportion of 1 year-old children immunized against measles	Intervention coverage	Medium/low; represents less than 10 per cent of the package for child survival	Health service provider registries in the public sector; household surveys
16. Maternal mortality ratio	Health outcome	High	Vital registration in countries with complete systems, sibling histories collected in household surveys
17. Proportion of births attended by skilled health personnel	Intervention coverage	High; but not the only intervention needed to reduce maternal mortality	Household surveys, definition of skilled health personnel varies across countries
18. HIV prevalence among women aged 15–24	Health outcome	High	Vital registration in countries with complete systems, modelling of mortality based on estimated sero-prevalence in other countries.
18a. AIDS estimated deaths			
18b. HIV prevalence rate, aged 15–49, percentage	Health outcome	High	ANC clinic sero-surveillance in sentinel sites, household sero-surveys; ANC sentinel surveillance overestimates national population prevalence
18c. HIV/AIDS prevalence rate for pregnant women 15–24 attending antenatal care in clinics in capital city	Health outcome	Low; represents only a partial fraction of the national prevalence, but has been used to estimate incidence of HIV	Capital city ANC sero-surveillance, because of variability in representativeness of sentinel clinics and demographic significance of capital city, comparability limited
18d. HIV/AIDS prevalence rates, men, estimated from national population surveys	Health outcome	Subset of 18b	Household sero-surveys
18e. HIV/AIDS prevalence rates, women, estimated from national population surveys	Health outcome	Subset of 18b	Household sero-surveys
19. Condom use to overall contraceptive use among currently married women, aged 15–49	Intervention coverage	Low; not a good measure of condom use in high-risk sexual intercourse	Household surveys
19a. Condom use, men aged 15–24 years at last high-risk sex	Intervention coverage	Medium; condom use for any age group for high-risk sex would be of public health interest	Household surveys but validity of reported rates of high-risk sex not established
19b. Condom use, women aged 15–24 years at last high-risk sex	Intervention coverage	Correlation coefficient with 19a in 2000 is 0.85	Household surveys but validity of reported rates of high-risk sex not established

(Continued)

Table 4.2.1 Continued

Indicator	Type of indicator	Public health importance	Measurement strategy
21. Prevalence and death associated with malaria			
21a. Malaria deaths rate per 100,000, ages 0–4	Health outcome	High	Vital registration in countries with complete systems, in nearly all endemic countries, based on verbal autopsy data for demographic surveillance sites, or epidemiological models
21b. Malaria deaths rate per 100,000, all ages	Health outcome	Low; death rates over the age 0–4 very low	Vital registration in countries with complete systems, in nearly all endemic countries, based on verbal autopsy data for demographic surveillance sites, or epidemiological models
21c. Malaria prevalence, notified cases per 100,000 population	Health outcome	Low; notified cases are not a measure of prevalence	Administrative data collected at health facilities
22. Proportion of population in malaria-risk areas using effective malaria prevention and treatment measures			
22a. Malaria prevention, use of insecticide treated bednets in population <5, percentage	Intervention coverage	High	Household surveys
22b. Malaria treatment, percentage of population <5 with fever being treated with antimalarial drugs	Intervention coverage	Moderate; resistance makes effective antimalarial drugs a better indicator	Household surveys, validity not established
23. Prevalence and death rates associated with tuberculosis			
23a. Tuberculosis death rate per 100,000	Health outcome	High	Vital registration in countries with complete VR, modelled for all other countries
23b. Tuberculosis prevalence rate per 100,000 population	Health outcome	High	No measurement strategy, modelled estimates based on case notifications
24. Proportion of tuberculosis cases detected and cured under directly observed therapy (DOTS)			
24a. Tuberculosis, DOTS detection rate, percentage	Intervention coverage	High	Health service provider registers for detected cases, no measurement strategy for denominator
24b. Tuberculosis, DOTS treatment success, percentage	Intervention coverage	High	Health service registers
31. Proportion of the population with access to improved sanitation, urban and rural			
31a. Water, percentage of population with access to improved sanitation, rural	Risk factor	Moderate; not clear whether separate indicators for rural and urban necessary	Household surveys
31b. Water, percentage of population with access to improved sanitation, total	Risk factor	High	Household surveys
31c. Water, percentage of population with access to improved sanitation, urban	Risk factor	Moderate; not clear whether separate indicators for rural and urban necessary	Household surveys
46. Proportion of population with access to affordable essential drugs on a sustainable basis	Intervention coverage	High	No measurement strategy

informative; and still others cannot be estimated at all or are subject to measurement errors and poor validation. For a health indicator to be measured successfully, public health specialists, information system experts, advocates, implementers, and funders need to concur.

Methods for community diagnosis

Health information systems

A *health information system* includes procedures to collect, store, analyse, transfer, and retrieve data or health metrics for

decision-making. The data may be stored in paper and/or electronic form, and the collection, analysis, transfer, and retrieval may be performed by human beings or electronic information technology, but usually by some combination of both. Advances in information technology, and the increase in the penetration of cellular mobile phones, offer opportunities to revolutionize information systems in low- and middle-income countries.

A combination of data from community and facility-based systems are used for community diagnosis. An ideal health information system is driven by community needs and provides sufficient feedback to district and local health planners for the purposes of decision-making, quality improvement, and planning. We shall describe these key data sources outlining their potential in low- and middle-income countries.

Household surveys

Household surveys are some of the most commonly used methods for documenting burden of disease, risk factor surveillance, and health expenditures. Often they are nationally representative and utilize a two-stage stratified sampling design. There are several resources on how to conduct health surveys (Institute for Health Metrics and Evaluation n.d.; The DHS Program n.d.).

Countries such as Kenya, Uganda, Swaziland, Thailand, Mexico, Brazil, Chile, and Columbia have incorporated biomarkers such as dry blood spots for HIV and other infections, into their household surveys (Central Statistical Office (CSO) and Macro International Incorporated 2008) at marginally higher costs.

Implementing surveys requires several considerations. Designing the questionnaire is the single most critical stage in the survey development process. As such, key questions to tackle include, but are not limited to: What is the question that the survey aims to answer? How do I design my survey instrument to capture information that will allow me to answer that question? Who is the target population? They are there a need to stratify the population? What is the sample size that is required to reach a scientifically sound conclusion? Is the sample representative?

In conducting surveys, communities must be active participants and must be engaged very early in the process. Inappropriate consultation with the community may lead to failure or may compromise the validity of the survey. However, when properly done, community mobilization and engagement can yield participation rates of up to 98 per cent (Central Statistical Authority (Ethiopia) and ORC MACRO 2001). Return of biomarker results and dissemination of results to survey participants is increasingly becoming an ethical requirement and needs to be considered.

The Multiple Indicator Cluster Surveys (MICS) are special surveys developed by the United Nations Children's Fund to provide internationally comparable, statistically rigorous data on the situation of children and women. They are particularly tailored to track progress towards the attainment of the MDGs. Using this method, it has been documented that 9 per cent of children under the age of 15 in sub-Saharan Africa have lost at least one parent (Monasch et al. 2004).

Where two-stage cluster sampling is not feasible, a single-stage cluster sampling may provide a reasonable alternative. With single-stage cluster sampling, an area is divided into non-overlapping units, called clusters. A limited number of clusters are randomly sampled for inclusion into the study, and then all units within the selected clusters are sampled. This has the advantage of avoiding costs of developing a sampling frame and

further enhances efficiency since it ensures that survey areas are limited geographically. One further advantage of cluster sampling is that it can be integrated with lot quality assurance sampling (LQAS) (Hoshaw-Woodard 2001).

Lot quality assurance sampling

In some instances, household surveys are either expensive or impractical. LQAS provides an alternative to identify priority areas or indicators that are not reaching average coverage at subnational level. LQAS can provide an accurate measure of coverage or health system quality at a more aggregate level (e.g. programme catchment area or district or refugee camp), typically called 'supervision area' and at a lesser cost. It can be used for quality assurance using a 'minimal sample', 'maximal security' principle. A typical sample size is five to six supervision areas each comprising 19 facilities. In Uganda, it has been used to assess the performance of HIV/AIDS control programmes at the district and subdistrict levels as well as at the national level. There are now several examples applying LQAS for ongoing supervision, and the most well-documented example is from a maternal and child health project in rural Nepal (Valadez and Devkota 2002).

A detailed description of the methodology and its application is available (Lemeshow and Stroh 1988; Myatt et al. 2003).

Vital registration

VR—the systematic recording of births and deaths—has both legal and health significance. Specifically, as an integral part of community diagnosis, VR enables countries to track health related targets of the MDGs (Liu et al. 2012). Specifically VR has been used, in combination with VA, to monitor stillbirth rates (Cousens et al. 2011) and adult mortality (Rajaratnam et al. 2010) and the overall impact of the Millennium Villages Project (Ohemeng-Dapaah et al. 2010). In HIV clinics, linking to VR systems can provide more accurate assessments of programme effectiveness and target lost patients most at risk for mortality (Foxet al. 2010).

VR systems are now fairly well established around the world with about 115 countries reporting death statistics to the World Health Organization in 2003 (Mathers et al. 2005). Although it is the ideal method for mortality estimation, many low- and middle-income countries have incomplete VR systems. In one study in Great Accra, the rate of under-registration of maternal mortality was 28 per cent, mainly due to misclassification (Zakariah et al. 2006). Nonetheless, interest in establishing sample VR, in which a subset of VR is studied, is rapidly growing in Africa and Asia.

Limitations

VR systems are expensive to set up and require close collaboration between Ministries of Health, and sectors responsible for registration of persons, immigration, and the judiciary. Misclassification of cause of death is a major drawback for VR. Adjusting for this can improve death registration data and provide empirical estimates of mortality (Birnbaum et al. 2011). Furthermore, statistical modelling can be used to estimate the causes of child mortality for settings with incomplete VR (Murray et al. 2010). Another means of improving measures of adult mortality is using sibling survival (Obermeyer et al. 2010).

Verbal autopsy

Cause-of-death data derived from VA are increasingly used for health planning, priority setting, monitoring, and evaluation in

countries with incomplete or no VR systems. Currently, the VA method is routinely used at over 35 sites, mainly in Africa and Asia. In Kenya, between August 2002 and December 2008, a total of 1823 VA interviews were reviewed by physicians. The patterns of mortality as determined by both methods showed a high burden of infectious diseases, including HIV/AIDS, tuberculosis, and pneumonia (Oti and Kyobutungi 2010).

However, since VA procedures vary from setting to setting and may include physician reviews and/or computer automated methods, these instruments must be standardized and assessed with rigour in order to make accurate national and international comparisons of VA data. Traditional means of comparing VA methods include specificity, sensitivity, and cause-specific mortality fraction (CSMF). At the Institute of Health Metrics and Evaluation at the University of Washington, Seattle, a further refinement of the assessment of VA methods has been done (Murray et al. 2011).

Fig. 4.2.2 outlines the process of conducting and interpreting VA, assigning cause of death, and calculating CSMFs (Soleman et al. 2006).

Limitations

Although it has challenges relating to level of subjectivity associated with physician reviews, and is time and resource intensive, VA may be useful in generating probable disease mortality trends in a community, particularly when applied over time and integrated in routine DSSs.

Demographic surveillance systems

Demographic surveillance—the process of monitoring births, deaths, causes of deaths, and migration in a population over time—is one of the cornerstones of public health research and community diagnosis. DSSs involve continuous longitudinal recording of demographic data usually within small geographically defined populations and on a regular basis. The periodicity of follow-up varies somewhere between monthly household visits (Indepth NETWORK n.d.) to about yearly

visits (Collinson et al. 2002; Razzaque and Streatfield 2002; Indepth NETWORK n.d.). However, for most of the DSSs the average visitation cycle is about three times a year. DSSs start with an initial census to define the baseline denominator population and thereafter continuously monitor this population at well-defined periods of time in order to observe changes or events that occur within the initial population. During the routine visits, vital events such as births, deaths, and migrations and, in some areas like Kisumu, Kenya, pregnancies and new HIV and tuberculosis infections are registered and monitored. DSSs may yield critical information regarding magnitude and determinants of mortality and since they collect more detailed information on risk factors for disease, DSSs may inform morbidity patterns in the community.

DSS sites have provided platforms for research on pneumococcal vaccines in Basse (Gambia), maternal mortality in Matlab (Bangladesh), non-communicable disease in Filabavi (Vietnam), and HIV/STIs (sexually transmitted infections) in Rakai (Uganda), insecticide-treated nets in Navrongo, Farafeni (Gambia), Ifakara (United Republic of Tanzania), Kisumu (Kenya), and Oubritenga (Burkina Faso). DSSs are critical for measuring impact of health interventions, for example, malaria (Alba et al. 2011), track mortality and morbidity patterns of internally displaced persons (Feikin et al. 2010), and through initiatives of pooling together DSS information (Indepth NETWORK n.d.) it is possible to generate new standardized mortality rates and life-tables (Sankoh et al. 2006).

Limitations

DSSs like many other surveys rely on self-report; this limitation can be overcome by supplementing self-reported with actual physical exam. Whether data from DSSs can be generalized is a matter of debate. In South Africa, maternal recall of vaccination through DSSs has been found to be comparable to information retrieved from the vaccination (Ndirangu et al. 2011) and from demographic health surveys (Hammer et al. 2006).

Routine information systems

Practically every country in resource-limited settings maintains some form of health facility information system albeit with varying degrees of complexity. Typically these systems are paper-based registers but if applied well, health facility records yield information on patient load, service utilization, and health system infrastructure. The number of indicators that health information systems can collect through health facilities is finite and limited by the information system infrastructure and availability of human resources. The determination of the extent of information that can be accommodated through facility registers requires delicate balance between the necessity of the information and the burden to healthcare providers.

Routine systems can be integrated in surveillance systems particularly for communicable diseases like polio, measles, or malaria. A sharp increase in facility reported cases for malaria may point towards an impending outbreak, and facilitate a prompt public health response.

Limitations

One major limitation for routine records is the selection bias where those with severe illness and those with resources are more likely to seek care. Moreover, since the population at risk cannot be determined through facility records, rates of disease and injuries cannot be calculated.

Opportunities for improving community diagnosis

Electronic medical records

In response to major global health challenges such as HIV and malaria, the years 2002–2012 witnessed unprecedented development assistance for health mainly driven by PEPFAR, the President's Malaria Initiative, the Global Fund for AIDS, TB and Malaria, and GAVI Alliance as well as the Bill and Melinda Gates Foundation. In order to document the attainment of ambitious targets by these agencies, innovative methods including electronic medical records (EMRs) have been devised to complement the traditional health information systems. EMR platforms can be expensive to install and implement in developing countries. However, open-source systems which are cost-effective and flexible are available, for example, Open Medical Record System (OpenMRS). OpenMRS has been implemented in several African countries, including South Africa, Kenya, Rwanda, Lesotho, Zimbabwe, Mozambique, Uganda, and Tanzania.

Box 4.2.2 Case studies of various initiatives to enhance utilization of electronic medical records in low- and middle-income countries

Stand-alone databases

The AMPATH in Kenya supports HIV treatment at Moi University and utilizes EMR. In a review of the system a comparison of the clinic before and after adoption of the EMR showed patient visits were 22 per cent shorter, provider time per patient was reduced by 58 per cent ($P < 0.001$), and patients spent 38 per cent less time waiting in the clinic ($P < 0.06$); clinic personnel spent 50 per cent less time interacting with patients, two-thirds less time interacting with each other, and more time in personal activities (Cherutich et al. 2012). The EMR has also vastly simplified the generation of mandatory reports to the Ministry of Health.

Internet-based medical record systems

The PIH-EMR system was created to support the management of drug-resistant tuberculosis in Peru. This system was built using the Linux operating system, Apache web server, Tomcat Java Servlet engine, and Oracle database. It supports clinical care, logistics such as assessment of drug requirements, and research studies.

Web-based collaboration and telemedicine systems (not specifically for HIV)

Satellite are using the cell phone network in Uganda to transfer data to a central site. Local healthcare workers collect data on Palm Pilots and then connect to a local, battery-powered server called a Wide Ray Jack. This server allows data to be sent to and from a central database via a cell phone modem. More information is at <http://pda.healthnet.org/>.

Box 4.2.2 provides case studies of application of EMRs in low- and middle-income countries (Fraser et al. 2004).

Advances in information technology and communications

Rapid developments in information technology have greatly reduced the costs of setting up information systems. Plans were announced to develop a laptop PC for US \$100 (Bray 2005). At the same time, Internet access is now relatively widely available in many developing countries (Peru, Ghana, Kenya, etc.) and there exists a broad range of robust and flexible devices to manage data, including personal digital assistants (PDAs) and smartphones. Indeed in Africa and the rest of the developing nations, mobile phone subscription penetration ranges from 53–79 per cent. There exist tremendous opportunities to improve health information systems and inject efficiencies in the methods and tools of community diagnosis. These include geographical information systems (GIS) and electronic medical records.

Geographic information systems

GIS are a combination of computer hardware and software used to store, manipulate, analyse, and display spatial or geographic data. GIS had been widely used in many disciplines such as agriculture, forestry, environmental engineering, and urban planning prior to its applications in public health. Today, more public health professionals are aware of the usefulness of GIS; spatial data in small areas are more readily available and technology is more easily accessible. GIS is an appropriate and practical tool for governments and other agencies to use in identifying regional disparities and for priority setting. It has been used to track spatial distribution of human resources, health services and diseases (Rutto and Karuga 2009; Simoonga et al. 2009; Cooke et al. 2010; Massey 2011), ongoing disease transmission (Murray et al. 2009), and inform the design of emergency obstetric services (Bailey et al. 2011). In Kenya, for example, the entire Northern Corridor highway was studied to characterize the 'hotspots' where transactional sex is concentrated and to provide estimates of numbers of truckers and sex workers and the volumes of transactional sex taking place on the highway (Ferguson and Morris 2007). An average of 2400 trucks parked overnight at the 39 hotspots were identified and mapped using GIS. As a consequence, the Kenya National AIDS/STD Programme in Kenya has instituted HIV prevention and treatment services along these 'hotspots'. In the Greater Mekong area, a hotspot mapping was able to determine the need for more comprehensive programming for the key population groups (sex workers, males who have sex with males, intravenous drug users, and people living with HIV/AIDS (USAID 2006).

By layering different types of HIV/AIDS-related information such as prevalence rates and behavioural surveillance, GIS technology allows this information to be integrated into a choropleth map (Fig. 4.2.3) and visually compared with other information, such as the programme response in a given area (Larmarange et al. 2011).

Conclusion

Community diagnosis and information systems are key ingredients for improving public health outcomes. Without appropriate tools and methods for community diagnosis, stakeholders may

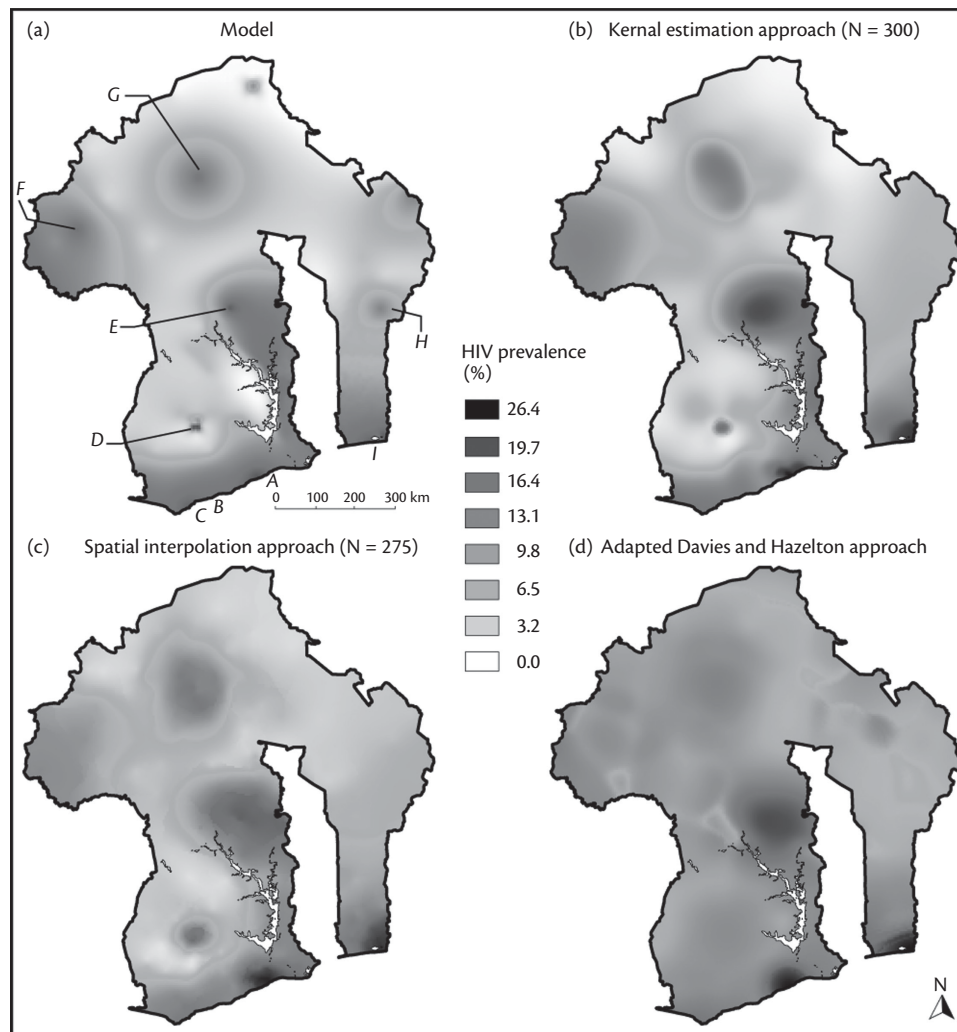

Fig. 4.2.3 Model prevalence surface and estimated prevalence surfaces using three different approaches based on the same DHS simulation.

Reproduced with permission from Joseph Larmarange et al., Methods for mapping regional trends of HIV prevalence from Demographic and Health Surveys (DHS), *European Journal of Geography*, Document 558, Copyright © 2001 CNRS-UMR Géographie-cités 8504, DOI: 10.4000/cybergeog.24606.

not have the means to document the burden of disease, identify risk factors for adverse health outcomes, and prioritize health interventions. However, none of the methods are reliable on their own and each should be validated and complemented by other methods to yield robust estimates of key health metrics. As the countdown to the MDGs for 2015 begins and as the international community prepares to set new targets beyond the MDGs, developing countries have to demonstrate, through robust methods and tools, that the burden of disease in their regions warrants further global attention. Therefore, low- and middle-income countries need to invest in these information systems and seize opportunities offered by increasing access to technology and the Internet to strengthen community diagnosis.

New communication technologies, social media, and public health

Mohan J. Dutta

Introduction to new communication technologies

New communication technologies play vital roles in the realm of public health, both in terms of contributing towards positive health outcomes as well as possibly generating a variety of adverse health effects. In recent years, the advent of web 2.0 technology has fundamentally shifted the terrain of how users and communities engage with technologies in communicating about health. As opposed to the earlier web 1.0 technology that sends out one-way communication through static pages, web 2.0 technology allows for users to both produce and distribute content (Thackeray et al. 2008, 2013). These new communication technologies have also been referred to as social media because of their fundamental nature of usage that is grounded in social and community networks, shifting traditional forms of sender-driven media uses towards more two-way forms of communication (McNab 2009). Social media, descriptive of participative media applications on the Internet, utilize the next generation of web 2.0 technologies to enable users to share, collaborate, link, and include user-generated content (Thackeray et al. 2008). The current repository of new technologies enables collaborative writing (blogs, wikis, etc.), sharing of content (Facebook, text, YouTube, Flickr), social networking (Facebook, Twitter), social bookmarking (ratings, tagging, etc.), and syndication (blogs, RSS feeds, etc.) (Thackeray et al. 2008). Essential then to the functioning of social media are the networks and ties within which they are embedded, in addition to their participatory characteristics that enable user active engagement, co-scripting, and active dissemination of content.

The important role of these new communication technologies in redefining the landscape of communication is often acknowledged in coining the term 'revolution' to depict the shifts in the nature of communication (Della et al. 2008). The powerful role of these new communication technologies has been acknowledged by public health and health communication scholars, attending to the broader connectivity in communities leveraged by the various forms of social media (Della et al. 2008; McNab 2008; Thackeray et al. 2008; Taubenheim et al. 2012). Health scholars have noted that new communication technologies democratize the landscape of health information processing by creating multiple loci of

health information dissemination, and by shifting the very nature of health information dissemination into the hands of publics.

However, simplistic depictions of the growth of these new communication technologies as cyber-revolution need to be tempered with nuanced attention to the complexities of social, cultural, political, and economic contexts that shape the penetration of, access to, and usage of these technologies globally. Also, discussions of the public health implications of these new communication technologies need to be based on detailed analyses of the complex social, economic, and political fabrics within which they are constituted. Geographically, for instance, there exist differential patterns in the penetration of new communication technologies that are similar to patterns witnessed in the diffusion of traditional media. In addition, within nation states, there exist differential patterns of uses of new communication technologies, mapping out along the lines of differentials in access by socioeconomic status (SES), age, and race.

The patterns of access to and usage of new communication technologies continue to mirror the inequities in patterns of media usage that are seen in the context of traditional media, thus risking the perpetuation of similar inequities in knowledge and behaviour often generated by health campaigns in the case of the traditional media. The growing body of research on the 'digital divide' points towards the differential patterns of access to new communication technologies. How then to conceptualize the broader public health implications of the growth of social media? In this chapter, attention will be drawn to the positive uses of social media for health promoting goals, followed by discussion of the adverse public health outcomes of social media.

Trends in social media

The trends in social media reflect growing user participation in creating, curating, and sharing content through the uses of new communication technologies. Globally, there has been an increase in social media usage among Internet users and this is particularly the case in low- and middle-income countries. Further, there has been a global growth in mobile technologies and the uses of these technologies for accessing information, posting content, tagging and sharing content, collaborating, etc. According to a Pew Global

Attitudes Survey conducted in 2011 across 21 countries, a median of 75 per cent of mobile phone owners say they text. Among the mobile phone owners, 50 per cent report that they take pictures/video and 23 per cent report that they use the Internet on their mobile phones (Pew Research Center 2011). The report also notes that social networking usage typically tends to be higher in higher-income countries as compared to lower-income countries. However, taking into account the obvious differences in Internet access between higher- and lower-income countries, people in lower-income countries that have online access are equally or more likely to use social networking sites as compared to people in higher-income countries (Pew Research Center 2011).

Texting is most common among mobile phone owners in Indonesia (96 per cent), Kenya (89 per cent), and Lebanon (87 per cent). Also in Poland, Mexico, Japan, and China, 80 per cent or more mobile phone users say that they regularly text. Regarding the usage of their mobile devices to access the Internet, at least 30 per cent in six countries, namely Israel, Japan, United States, Britain, China and Poland, go online using their phone. In 15 countries among the 21 countries polled, at least 25 per cent of those polled note having visited a social networking site. Social networking usage is highest among the respondents in Israel and the United States, with more than 50 per cent of respondents stating that they use a social networking site. In Britain, Russia, and Spain, more than 40 per cent of the respondents note that they use a social networking site. Growth of social networking was highest in Egypt and Russia, two countries that experienced a great deal of political participation through social media, and was approximately 10 per cent, growing from 18 per cent in 2010 to 28 per cent in 2011 in Egypt, and growing from 33 per cent in 2010 to 43 per cent in 2011 in Russia.

Globally, there is increasing participation of Internet users in social media. On the basis of a US-wide survey conducted in August 2012, Rainie et al. (2012) observed that 46 per cent of Internet users post original photos and videos that they themselves have created, and 41 per cent of adult Internet users repost photos and videos that they have found online. These creators and curators comprise a major segment of the US population of Internet users, playing an active role in constituting online content. Currently, approximately one-third of adults utilize health-related social media (Taubenheim et al. 2012). Furthermore, individuals who seek out health information online are also likely to use a wide variety of social media such as blogging, using Facebook and using other status update services (Fox and Jones 2009; Hughes 2010).

Online support groups

The earliest forms of social networking platforms that became vital health communication tools were online social support groups. These online support groups emerged as communities in the virtual space where patients and their family members could interact, exchange information about diseases and their treatments, and seek out solutions through participation.

Facebook

Facebook is a social networking site that enables users to post information, share information, tag and rate resources, and form groups based on interests. In the United States, in a survey conducted nationwide between 2 and 5 August 2012, 66 per cent of all Internet users used Facebook (Rainie et al. 2012). Along the lines

of gender, 63 per cent of Internet users among men and 70 per cent Internet users among women reported having used Facebook. The highest percentage of Facebook users was in the 18–29 age group (83 per cent) compared to 40 per cent of Internet users in the 65+ category, suggesting that Facebook is more likely to have a younger audience.

Twitter

Twitter is a social messaging service that allows the instant dissemination of information between publics across the world. Users can post their own ‘tweets’ as well as follow health information, developing health stories, health conferences, etc. They can also search for health information on Twitter, resulting in new information, contacts, and networks. In the same survey in the United States reported earlier, 16 per cent of Internet users in the US reported using Twitter (Rainie et al. 2012). The Singapore Health Promotion Board uses Twitter to reach out to its audiences with health information and has 2266 followers. The World Health Organization utilizes Twitter to disseminate information to a wide net of globally distributed audiences.

Podcasts

Podcasts are voice-recorded information resources that can be downloaded from the web. Multiple health agencies and institutions such as the US Centers for Disease Control and Prevention (CDC), Mayo Clinic, Harvard’s School of Medicine, the World Health Organization, the Public Broadcasting Service, and HealthBeat utilize podcasts to reach out to their audiences. Many of these health information podcasts are available for free from iTunes or can be downloaded directly from the respective websites. According to the study published by Della et al. (2008), CDC had published over 250 podcasts by 2008, and the podcasts had been downloaded more than 180,000 times.

YouTube

YouTube is a video networking and video-sharing website, where users can upload, view, and share videos. Video materials posted on YouTube include movie clips, TV clips, music videos as well as video blogging (vlogging) and short original videos. On 3 October 2012, 29.39 per cent of Internet users globally used YouTube, with an Alexa Traffic Rank of third globally and in the US (Alexa n.d.). According to the same report, roughly 20 per cent of visitors to YouTube come from the United States. The Singapore Health Promotion Board utilizes YouTube to post its video content of health promotion campaigns. For instance, The Bepositiveproject campaign has a YouTube page that posts the video materials of the campaign, with 299 subscribers and 137,556 video views (TheBepositiveproject n.d.). The campaign page has 15 videos, and audience members post comments on the YouTube videos. Similarly, the ‘Let’s Stop HIV Together’ campaign in the United States targeting Americans with the message of HIV prevention ran multiple YouTube videos (Centers for Disease Control and Prevention (CDC) n.d.). The videos generated a great deal of viewership, resulting in over 130,000 views. The CDCStreamingHealth YouTube page has over 14,000 subscribers and more than 25 million video views, posting health information and prevention-based resources on the page (viewing data from 5 November 2013).

Blogs

Blogs are user-driven informational and discussion sites where users design and craft content, organized as distinct entries in reverse chronological order. Blogs can be single authored or multi-authored, and are considered a form of social media because most posters not only provide content on the blog but also share this content in a social network, engaging with their readers as well as other bloggers. According to a Nielsen report published in 2011, there were 156 million public blogs in existence by February 2011 (Nielsen 2011a). In the United States, in May 2011, Blogger reported over 50 million unique visitors and Wordpress reported over 22 million unique visitors (Nielsen 2011b). In 2006, the CDC launched the *Health Marketing Musings* blog on its Health Marketing website, fostering a space for health marketing professionals to publicly discuss relevant communication and marketing strategies (Della et al. 2008). The CDC website provides a listing of all the blogs posted by CDC, now adding up to 13 blogs on various topics. For instance, the *Global Voices* blog provides information on health initiatives from across the globe. In the United States, among 41 per cent of users of Blogger, household income is greater than \$75,000, and 25 per cent of visitors to Wordpress have a Bachelor's degree.

mHealth

mHealth is the delivery of health related services via mobile communications technologies such as mobile phones and PDAs (United Nations Foundation 2009). In nations where shortage of workers continues to be a key problem and the penetration of mobile communication technologies is high, mobile health services offer important avenues for reaching out to underserved audiences, especially in hard-to-reach and resource-poor environments. In areas where access to medical services is the key challenge, mobile technologies offer health workers means for providing diagnoses as well as real-time health information. Health clinics, home providers, and health workers can rely on these technologies to secure quality health information in their delivery of care. mHealth programmes can also serve as resources for digitizing patient health records into national health systems, thus standardizing these health records and creating a national-level inventory. The United Nations Foundation report cited earlier documents 51 mHealth programmes in 26 different countries including India, South Africa, Uganda, Peru, and Rwanda, offering the following functions: (1) education and awareness, (2) remote data collection, (3) remote monitoring, (4) communication and training of healthcare workers, (5) disease and epidemic outbreak tracking, and (6) diagnostic and treatment support. In the backdrop of the digital divide, these mobile communications technologies also serve as avenues for reaching out to resource-poor audiences through mobile devices that are accessible. For example, Project Masiluleke and Text to Change utilize SMS message campaigns to provide HIV/AIDS education in South Africa and Uganda, respectively. In Georgia, a film on HIV/AIDS created by Save the Children and UNICEF with the goal of educating the youth was disseminated via mobile phones, encouraging the youth to pass it on to others. Similarly, the Freedom HIV/AIDS games launched in India in December, 2005 run on mobile phones and have been created with the goal of fostering HIV/AIDS awareness through the 'play-and-learn' method. Within 4 months, 10 million games

had been downloaded, many of them having been downloaded in cities and towns where the vulnerability is higher.

Social media as health resources

Social media usage is constituted amid various forms of functions offered by social media as resources. These forms of user-driven collaborative media on the Internet have shifted the ways in which traditional mediated communication takes place, turning mediated communication into a two-way process where users have an active role to play (Thackeray et al. 2008; McNab 2009). A resource-based approach to social media examines the communicative functions played by social media, drawing upon the argument that social media play different functions in different contexts, and the specific uses of social media are driven by the needs felt by the user at a given point of time. Social media as resources for health operate across a wide variety of functions, meeting a wide variety of health needs of users. Whereas social media differ substantively from traditional forms of media in terms of audience participation, in other ways, social media are very similar to traditional media in their information dissemination functions. In the United States, the use of social network sites has multiplied over the last decade (Jones and Fox 2009; Pew Internet and American Life Project 2012). Also, in other parts of the globe, increasingly Internet users have become social media users, with a large percentage of Internet users from low-economic development countries being social media users.

Social media as social capital resources

Broadly, social media are defined as the category of Internet-driven media platforms that involve collaboration and sharing. On social media, audience members participate actively in posting content, in commenting upon content posted by others, in sharing information-based resources, and in having conversations about ideas or causes that are of interest to them (Chou et al. 2009; Hughes 2010). As opposed to traditional media that are typically static in content encoded by a sender to be decoded by a receiver, social media are dynamic and context-driven, creating opportunities for co-creation of communication. Co-creation refers to a partnership among multiple participants, where they come together to engage in mutually meaningful communicating. As a result, communication emerges through interactions on social media, taking on varying interpretive frames based on social interactions among participants on the media platform.

The capacity of social media to catalyse communication within and across social networks is critical to the role of social media in generating social capital, referred to as the collective participatory strands and networks of trust within communities. Social media enable the formation of social capital through the specific linkages that it fosters among community members. It enables the formation of communities in virtual spaces that are not restricted by geographic boundaries and other structural features. For instance, a specific community formed on a social medium develops into a resource for the community, enabling participation and collaboration virtually among community members. Online health communities for example have emerged as vital resources for social support for acute as well as chronic disease patients and their families. The American Cancer Society operates multiple

community forums that are disease specific, and that emerge as resources for community members, sharing information, guiding each other, offering emotional support, providing guidance in the context of decision-making, mobilizing resources collectively, etc.

Also, in the realm of health campaigns, the social capital generated on social media emerges as a channel for disseminating health information as well as for building communication networks for the dissemination of preventive health information resources. The trust and credibility of health communication messages increase when the messages are embedded within interpersonal and community networks. The Heart Truth campaign launched by the National Heart, Lung, and Blood Institute utilizes a variety of social media in order to connect with audience members, leveraging the strong social networks and social support resources of women to empower women and to educate them about heart disease, their number one killer.

Launched in 2008, The Heart Truth Facebook fan page (The Heart Truth n.d.) gained over 3500 fans by early 2011. By November 2013, the page had over 38,000 'likes'. Fans participate in conversation with the materials posted by the team, and interact with the content through 'likes', through the posting of their own comments in response to the materials posted by the campaign team, and sharing the information posted on the Facebook page on their own Facebook pages. Pieces of information shared by the campaign team become the basis for additional sharing of resources among community members on the Facebook page, this leading to the widespread dissemination of the information. Along these lines, tweets offer ways of connecting user communities through key pieces of scientific and/or health information, and blogs also serve as important social capital resources by connecting individuals and communities into networks.

Social media as information resources

Social media have high levels of reach, and therefore, serve as important tools for the dissemination of information, leveraging the multiplicative reach of social networks to disseminate information. One of the key elements of contemporary health communication is the need for health information capacity building, developing resources that enable participation in healthcare decision-making. Social media such as Facebook and Twitter can play important roles in building the information capacities of publics, making science and scientific decision-making processes more widely accessible to the public, and enabling public participation in the utilization of science. For example, comparative effectiveness information on effects, side effects, risks, and costs of various preventive and treatment options can be disseminated widely through the leveraging of social media. The emphasis on comparative effectiveness information seeks to democratize the nature of health decision-making, driving decision-making on the basis of systematic evidence on effectiveness, risks, side effects, costs etc.

Take the example of the World Health Organization (WHO). The WHO uses tweets to reach out to global publics with health information, reaching over 900,000 'followers' (World Health Organization n.d., viewing data from 5 November 2013). During the H1N1 pandemic, the WHO leveraged the social networking function of Twitter to disseminate information to geographically spread audiences. Information posted on Twitter is then followed by audiences, thus embedding the information within social

networks. In addition, the 'retweet' function allows interested audience members to share the information with others, thus disseminating the information further through social networks.

Similarly, the Health Promotion Board in Singapore, a government agency that works on dissemination of health information and promotion of healthy behaviours, runs a Facebook page (Health Promotion Board, Singapore n.d.). As of November 2013, the Facebook page of the Health Promotion Board had over 97,000 likes. The Board utilizes the Facebook page to disseminate health information. For instance, it offers information on breast cancer detection in the month of October, synergizing with the Breast Cancer Awareness Month. One of the Facebook postings notes that breast cancer is the most common cause of cancer among Singapore women and early detection can save life. The posting then provides a detailed image of breast self-examination and walks the participant in depth through the various steps of self-examination. It connects to a webpage posted by the Health Promotion Board on its website, discussing the risk factors, the importance of breast self-exams and mammograms, and the basics of treatment.

Social media as channels of persuasion

A growing body of research suggests that social media are important channels of persuasion, based on the argument that involved audiences that participate in co-creating the persuasive messages are more likely to be persuaded by those messages as compared to audiences that receive top-down persuasion messages (Thackeray et al. 2008; Taubenheim et al. 2012). Social media are therefore being used as vital resources in health campaigns on a variety of topics ranging from suicide prevention to heart health promotion, and also for the purposes of promoting dialogues among campaign planners and the broader public health community (Hughes 2010; Taubenheim et al. 2012). Strategic uses of social media for health campaigns involve the deliberate consideration of digital goals and objectives, segmenting and prioritizing audiences, and optimizing the content of the strategic communication effort by listening to and engaging audiences in bidirectional conversation (Taubenheim et al. 2012).

The Think HIV: This Is Me campaign was launched by MTV and the Kaiser Family Foundation in the United States, encouraging youth aged 15–25 to become video bloggers by developing video content on the impact of HIV on their lives. Based on about 200 hours of video footage submitted by nearly 100 audience members in the target segment, the show *Think HIV* was created and aired four times by MTV, receiving more than 3 million viewings (Hoff et al. 2008). In the United States, The Heart Truth campaign launched by the National Heart, Lung, and Blood Institute in collaboration with Ogilvy Public Relations Worldwide utilized social media to: (1) increase women's awareness that heart disease is a leading cause of death; and (2) encourage women to find their personal risks, talk to their doctors, and take action to lower heart disease. The digital component of the campaign sought to: (1) connect women to create an online community, (2) motivate women to take action through online tools, and (3) promote partnerships for amplifying the campaign message through content integration and online engagement. Outreach to bloggers, launching a Twitter handle, developing a Facebook fan page, creating a Bit.ly account, utilizing Flickr, developing a YouTube presence, and developing Widgets and Badges were all components of the social media strategy of the campaign. The campaign has been successful in

fostering a women's health community, and in generating greater awareness of The Heart Truth campaign. After considering the possible influences of extraneous variables and secular trends, Taubenheim et al. (2012) report the increase in awareness regarding heart disease among women throughout the campaign period, along with increases in preventive action and decreases in heart disease deaths among women.

In New Zealand, the Txt2Quit campaign utilized text messaging along with an interactive web-based intervention to target people trying to quit smoking. Audience members could receive automated messages on quitting and text 'crave' and 'slip up' to receive instant messages with tips. Similarly, the Health Promotion Board in Singapore launched social media components of its 'Beat the Blues' campaign, posting campaign messages on Facebook and driving user-generated discussion, tagging, sharing, and participation.

Social media as resources for listening

Not only are social media important in reaching out to audiences with relevant and necessary health information, but they are also vital tools for listening. The difference between social media and traditional media lie in the specific ways in which social media are actively used by audience members, emerging as content-generating and content-sharing tools in communities. Given the active participation of individuals, families, and communities on social media platforms, media such as Facebook and Twitter also become vital avenues for listening to the voices of the people, creating active contexts for content to be co-produced. The traditional top-down nature of public health programming can be countered by the active role of social media in tapping into the voices of people and communities, and in fostering communicative avenues for them to participate in. The National Library of Medicine (NLM) utilizes its Facebook page as a platform not only to disseminate information, but also to listen to community members and to engage in dialogue. For health organizations that typically serve as repository of health information and perform the traditional function of information dissemination, social media open up opportunities for listening to communities, for engaging them in dialogue, and for co-constructing solutions. The NLM not only posts information on the Facebook site, but also responds to comments posted by users, thus creating a thread of dialogue.

Social media as avenues of expression and performance

Because of the content generating role of social media, they also emerge as communicative avenues for expression and performance, thus connecting biomedical narratives of health with lived experiences, stories, and frameworks of meanings among users. Social media enable authorship and participation by audiences. For instance, patients undergoing treatment utilize blogs and Facebook to communicate about their health, to interpret health information, to connect such information with their lived experiences, to make sense of their lived experiences in the backdrop of the information, to make a variety of health-related decisions, and to share this information with others.

Social media as advocacy and activist resources

Social media are not only critical in the dissemination of information guiding individual behaviour and lifestyle choices, but

are also pivotal to the organizing of advocacy and activist efforts directed at bringing about transformations in unhealthy policies. In the backdrop of contemporary globalization politics, it is particularly relevant to draw attention to the inequalities produced by economic liberalization, and the health consequences of these inequalities. For example, large-scale disparities in health outcomes are observed between the haves and have-nots in the global South. Similar discrepancies are witnessed in the global North as well. Even in nation states where growth rates are high, high Gini coefficients draw attention to the landscape of inequalities. Of particular importance for public health are the negative consequences of large-scale liberalization based on the principles of trickle-down economics.

Challenging the taken-for-granted assumptions around trickle-down, global activist movements draw attention to the increasing inequalities that have been produced by trade liberalization and opening up of markets. With the global rise in inequalities accompanied by rising unemployment, rising food prices, and rising displacements of the poorer and middle classes, the social media have emerged as sites of organizing, creating innovative avenues for connecting multiple stakeholders, drawing attention to information that is typically absent from mainstream media, and organizing resistance in opposition to inequitable structures. The interactive storytelling feature of social media has emerged as a key resource in the sharing of stories of adversity and economic hardship, co-creating a story of inequality that becomes the organizing feature for social change processes globally. For example, the Occupy Wall Street movement emerged in the United States and globally in response to the rising inequalities, the growing unemployment, the impoverishment of the middle class, and fundamental lack of basic resources (Dutta 2012).

Public health implications of social media

Social media also need to be examined in the context of their public health implications, especially as they relate to the adverse health implications of social media usage. For instance, with the absence of adequate regulatory processes that evaluate the quality of health information being circulated on social media, it is important to consider the health implications of circulating information that is not grounded in the evidence base. Another domain of interest to public health is the prevalence of unhealthy branding tactics on social media, especially in avenues that are directed towards children. Also, given the multiplicity of authors of health information in social media spaces, it is critical to consider the role of quality of health information in guiding health decision-making by publics. Along similar lines, given the variety of interpersonal communications that are generated on social media, it is important to consider the health implications on negative interpersonal communication such as cyberbullying and sexting.

Food marketing on social media

The food and beverage industry has adopted social media on a large scale to reach out to their target audiences. The strong food industry in the United States, for instance, spends US \$1.6 billion every year targeting young people (Richardson and Harris 2011; Yale Rudd Center for Food Policy and Obesity n.d.). Facebook and Twitter have emerged as key channels for reaching out to

large segments of consumers, especially in the youth segment (Richardson and Harris 2011). Richardson and Harris (2011), in their content analysis of Facebook campaigns launched by the food and beverage industry, noted that Coca-Cola is the most popular Facebook brand and Starbucks is the third-most popular Facebook brand. Also, the brands Red Bull, Monster, Dr. Pepper, Oreo (#4), Skittles (#8), Pringles (#11), Ferrero Rocher (#14), and Nutella (#16) ranked among the top 20 most popular brands on Facebook.

Especially given the high penetration of the Internet and social media among the younger segment of the population, one of the key strategies in food and beverage marketing is the strategic utilization of social media such as Facebook. For example, Cheerios runs a Facebook page that is targeted at children. The Facebook page depicts imagery of children, and utilizes the tagline 'Your moments. Our timeline. The story of Cheerios, as told by you' (Cheerios n.d.). Interactive storytelling, a key feature of social media, is strategically utilized to promote Cheerios. Audience ownership of storytelling is utilized in order to embed the brand Cheerios into the everyday lives of children. The Cheerios campaign utilizes language such as 'community building' and 'participation' in order to market the product.

On a similar note, the Facebook campaign of Coca-Cola has over 75 million 'likes' and uses localized storytelling to narrate the stories of users, sharing their stories about consuming Coke (Coca-Cola n.d., viewing data from 5 November 2013). Consumers post their stories of drinking Coke along with their images. These stories and images are embedded within images of Coke logos on the Facebook site of Coke. The images then serve as spaces for co-constructive storytelling, with users sharing the images, posting their comments, posting additional stories in response in the 'Comments' section etc.

Also, social media such as Facebook emerge as interactive storytelling sites for global brands, targeting the campaign to the local culture, and simultaneously drawing upon culturally specific strategies through participation of communities in country-specific campaigns. For example, the Facebook McDonald's Malaysia page has over 1.7 million 'likes,' as recorded in November 2013 (McDonald's Malaysia n.d.). The site emerges as a space for organizing contests, getting consumers to take pictures of trying out products, and sharing stories that are shared by consumers. The McDonald's brand is reinforced among consumers through the various Facebook stories and participatory tools that are utilized by consumers. Pictures of winners of different contests such as the Egg McMuffin Photo Contest on Instagram are then posted on the Facebook site.

Social media and existing disparities

Because social media are much more likely to be used among audience segments with higher levels of education and income, what are the consequences of developing social media-based messaging systems and strategies that don't attend to the inequities in access and usage (Chou et al. 2009; Lustria et al. 2011)? Furthermore, as reported in a series of health communication studies on health information seeking, extant research documents that more health-oriented segments of the population are also more likely to seek out health-based information resources on the Internet and utilize more information-heavy resources (Dutta-Bergman 2003). Given the active focus of social media, the relationship between health-orientation and health-based social media usage is critical

to examine, with attention paid to the role of social media in the context of health disparities. This is especially important in the light of the existing disparities in the penetration of social media globally and within countries.

In sum, without the critical consideration of the specific patterns of usage of social media, especially among hard-to-reach segments of the population, a one-size-fits-all approach is unlikely to reach out to the underserved and hard-to-reach segments of the population. A celebratory and uncritical stance towards social media as a resource for public health is likely to exacerbate health disparities rather than ameliorate them. What is the role of social media in the context of existing structural disparities within social systems? How are social media situated in relationship to the broader structures of social systems?

Social media and health

With the increasing participation of the public in social media platforms for health-related functions, attention needs to be drawn to questions of privacy and confidentiality (Pinnock et al. 2007). To what extent do social media participants understand the issues of privacy when sharing health information and the consequences associated with the various levels of privacy? What are the norms of privacy in the context of health information that are shared in social media platforms? Similarly, the increasing use of mobile technologies for health-related purposes raises concerns about health data security and confidentiality (Patrick et al. 2008).

The sharing of health information at multiple interfaces ranging from uploading of the information from a mobile device, linking it to a server, transmitting it to some form of electronic medical record, use and interpretation of the data by care providers, and the delivery of health information back to the patient involve multiple levels of information sharing, each with its corresponding issues of confidentiality. Noting the lack of guidance for professionals on the safe use of mobile phone technology for the delivery of healthcare, Pinnock et al. (2007) outline the need for national and international policies that guide and regulate mobile technology use, transfer of health-related data, and the status of health consultations that are offered through mobile technologies.

In addition to issues of privacy and confidentiality, it is also worthwhile to consider the quality of health information shared on social media and in peer-to-peer networks. For example, Syed-Abdul et al. (2013) noted that a large number of YouTube videos promote misleading information about anorexia nervosa, and that pro-anorexia videos are more highly favoured and rated by viewers as compared to informative videos. The widespread use of social media also increases the likelihood of dissemination of non-credible and potentially erroneous information (Kortum et al. 2008; Habel et al. 2009). Use of mobile health devices is also related with repetitive strain injury, a painful condition that can result in disability because of repeated movements (Karim 2009). 'BlackBerry thumb', for instance, results from the repeated use of the thumbs to type on the small keyboards that accompany many mobile devices.

Social media and interpersonal communication

A growing body of research is starting to document the negative interpersonal and social consequences of social media, especially

in the context of bullying, clique-forming, and sexual experimentation, manifesting in the forms of issues of cyberbullying, privacy management, and sexting (Patchin and Hinduja 2006; Hinduja and Patchin 2007; Lenhart 2009; MTV 2009; O'Keefe et al. 2011). In a 2009 survey conducted among 1247 respondents in the 14–24 age range, 50 per cent of young people reported having experienced some form of digital abuse (MTV 2009). The social networking capacities of social media can also become tools for bullying, perpetuating forms of exclusion and harassment. The anonymity on social media can contribute to cyberbullying, with important health consequences. Moessner (2007) defined cyberbullying as 'the use of the Internet, cell phones or other technologies to send or post text or images intended to hurt or embarrass another person' (p. 1).

A study analysing the 'Growing Up with Media' survey reported by Ybarra et al. (2007) observed that youth who were targets of rude and nasty comments or rumours being spread about them online as well as offline were more likely to experience distress by the incident as compared to youth who were targeted only in the online environment. The study also reported that 64 per cent of youth who were harassed online did not report being bullied at school. Most importantly, youth who were harassed online were also more likely to ditch or skip school as well as carry weapons to school. Youth who reported being harassed online were eight times more likely as compared to all other youth to concurrently report carrying a weapon to school in the past 30 days.

Wolak et al. (2007) reported that nine per cent of the 1499 youth surveyed were harassed online in the past year, and in this group, whereas 43 per cent were harassed by known peers, 57 per cent reported being harassed by online-only contacts. For targets of online-only harassments, the extent of distress experienced is much more likely to be higher when the harassment is repeated, when the harasser was 18 years or older, and when the harasser asked for pictures. In the opening commentary in the *Journal of Adolescent Health*, guest editors David-Ferdon and Hertz (2007) note that new media technologies are increasingly becoming sites of harassment and aggression, and therefore electronic aggression is becoming a public health problem, calling for additional prevalence and aetiological research to guide the development of interventions.

Theories of new media

The communication literature has developed a range of theories for understanding the uses and distributions of media, ranging from small-scale micro-level theories to large-scale macro-level theories. Whereas some of these theories focus on individual-level explanations for the usage of particular media types, other theories offer societal-level descriptions of uses of media.

Selective processing theories

Based on the notion that publics are inundated with media messages around them, selective process theories suggest that individuals attend to, cognitively process, and retrieve mass media messages that are consistent with their own attitudes and beliefs (Dutta-Bergman 2004a, 2004b; Della et al. 2008). Drawing upon the principles of selective processing, existing scholarship documents systematic within-population differences in audience interest in health issues. This body of research empirically documents

intrinsic differences in interest in health issues, captured in the concept of health orientation. Health-oriented individuals are more likely to search for online health information, and make decisions on the basis of this information. Reflecting the functional approach to media use, selective processing theories suggest that individuals orient their attention to specific stimuli in their environment, selecting and processing information that is consistent with existing attitudes and beliefs, and avoiding information that is discrepant with their existing dispositions (Atkin 1985; Zillman and Bryant 1985).

Selective processing of media messages plays out in the context of selective exposure, interpretation, and memory (Oliver 2002). Selective exposure theory suggests that audiences select media messages that match their existing attitudes and beliefs based on the notion that individuals seek consistency in their cognitions (Webster and Wakshlag 1985; Oliver 2002). Selective perception theory suggests that readers and viewers ascribe meanings to and judgements of media messages that are consistent with their existing values and beliefs. Also, pre-existing beliefs and attitudes influence what is remembered by audience members (Oliver 2002). In the context of health information processing, Dutta-Bergman (2004a, 2004b) demonstrated that health-active individuals that are highly engaged in health-related issues are more likely to seek out health specialized media content as compared to the individuals who are not involved in issues of health. In other words, an intrinsic interest in health issues is tied to the active seeking out of health information resources.

In the context of social media then, it may be argued that health-oriented individuals who are intrinsically interested in health issues are also the ones that attend to health-related social media. Furthermore, healthcare consumers selectively orient their attention to specific health-based social media resources that match their existing interest in health issues. This is particularly the case with the social media where the choices of social media as well as the specific groups selected are driven by an active interest in specific issues and topical areas. The two-way communication enabled by web 2.0 facilitates selective processing of information such that the participation in specific Facebook sites and interactions is driven by an intrinsic interest in the topical area. Health-motivated public who are intrinsically interested in health issues are also likely to seek out health-related social media such as specific Facebook sites and blogs, remember specific aspects of health messages aligned with their intrinsic interest, and then act on the knowledge gained through this process.

Uses and gratifications theory

Founded on the principles of an actively engaged audience, the uses and gratifications perspective conceptualizes media consumption in terms of the specific functions served by the media (Katz et al. 1974; Rubin 1994). This line of research suggests that media serve a wide variety of functions for different segments of the population, and the consumption of media is driven by the choice patterns of receivers (Rubin 1994, 2002). Beginning with developing a framework for understanding the felt needs of the audience, the uses and gratifications framework argues that these felt needs drive specific forms of media consumption.

According to Katz et al. (1974), the uses and gratifications framework seeks to: (1) explain how people use media to satisfy their needs, (2) understand motives underlying media behaviour, and

(3) identify functions or consequences that emerge from the intersection of needs, motives, and behaviours. Rubin (1994) suggests five core elements of uses and gratifications research: (1) communication behaviour is goal-directed, (2) individuals select and use communication channels to satisfy felt needs, (3) individual communication behaviour is mediated by a plethora of social and psychological factors, (4) media compete with other forms of communication, and (5) although individuals are typically more influential than the media in the relationship, this is not always the case. Audience members systematically differ in their motives for information, surveillance, entertainment, habit, social interaction, escape, pass time, and relaxation from the consumption of specific media, and they satisfy these motives by building a repertoire of media they consume.

Extant research demonstrates systematic differences in motives for consuming new communication technologies (Palmgreen and Rayburn 1982; Becker and Schoenbach 1989). In a national random-digit-dialling telephone survey conducted in 1994, Perse and Dunn (1998) reported that home computers were typically associated with ritualistic uses such as keeping busy and passing time. In addition, such ritualistic use was positively related with greater computer use. On a similar note, Parker and Plank (2000) reported that university students were primarily using on-line sources for relaxation and escape. Ferguson and Perse (2000) observed the salience of entertainment as a motive for visiting the World Wide Web among college students. The most visited web sites were sports and entertainment websites. Also, another important motive for using the web in the college sample was acquisition of information. Kargaonkar and Wolin (1999) reported that web usage was positively correlated with social escapism, information, interactive control, and socialization motivations. Papacharissi and Rubin (2000) similarly demonstrated that information seeking and entertainment were the most salient motives for using the Internet.

Theory of channel complementarity

What is the relationship between traditional and new media? The theory of channel complementarity suggests that new media consumption patterns mirror consumption patterns of traditional media, thus reiterating the existing forms of access and usage (Dutta-Bergman 2004c, 2004d, 2004e). Media consumption is driven by intrinsic interest in a specific content type, and therefore, consumption of traditional media is complementary to consumption of new media, grounded in notions of active participation. Therefore, there exists a positive relationship among the usage of different communication channel types that share similar functions and serve similar needs for their audiences (Stempel et al. 2000; Dutta-Bergman 2004c, 2004e). Channel types that offer similar functions for the consumer exist in complementary relationships, such that the usage of one channel type is reinforced by the usage of another channel type. These complementary patterns are reported by Stempel et al. (2000), who noted that Internet users were also more likely to be newspaper readers and radio news listeners. Also, LaRose and Atkin (1992) observed that the use of local audiotext information services was complementary with the use of similar information technologies such as videotexts, ATMs, 800 numbers, and telephone answering services that shared the function of providing information on demand to the user.

Channel complementarity in content areas is observed because of high consumer involvement in the content area (Dutta-Bergman 2004c, 2004d; Rice 1993). People using one particular medium to gather information in one particular area are also likely to use other media to gather information in that area. In the domain of health, the health-motivated consumer who is intrinsically interested in issues of health is not only likely to read health magazines and health-related sections of news, but is also likely to watch health television, surf health-related websites to gather health information, and participate in health-related social media. Underlying the consumption of health content across these various channels is an enduring consumer interest in health (Dutta-Bergman 2004c, 2004d). Dutta-Bergman (2004c) observed that use of the Internet for science and health information was congruent with the use of traditional media for science and health information.

In this sense then, new media extend traditional media consumption patterns, thus replicating existing disparities in knowledge as well as health outcomes. Tian and Robinson (2008) observed that cancer patients and non-patients utilize traditional media, the Internet, and face-to-face communication to gather health information. Complementary patterns therefore extend beyond the media context to interpersonal and community contexts, such that health information seekers in online media are also more likely to seek out health information from interpersonal contexts. Similarly, participation in offline communities is likely to be correlated positively with participation in online communities.

Diffusion of innovations

The diffusion of innovations framework offers an organizing lens for understanding the ways in which a new technology spreads within a population (Rogers 1995). The framework lends itself especially well to the study of social media because of the community-driven and network-based nature of social media. Rogers (1995) outlined specific characteristics of an innovation such as relative advantage, compatibility, trialability, and observability as pivotal in shaping the diffusion process. Furthermore, the innovation gets adopted differentially among different segments of the population, ultimately spreading across the population. The earliest users of the innovation are called adopters, individuals who are eager to try out new products and have strong social networks. These adopters play key roles in the dissemination of the innovation across the population. In the case of social media, early adopters link others in their network to social media platforms, thus driving the diffusion of these platforms.

The culture-centred approach

The culture-centred approach (CCA) attends to the role of communication in enabling the active participation of individuals, families, and communities in health-related decision-making. It notes that communication is an active meaning-making process that is constituted in relationship with organizational and societal structures. Structures refer to the ways in which resources are organized in societies and in the institutions and organizations within them. Access to communication avenues mirrors patterns of access to other structural resources such that those segments of society that are historically disenfranchised in their access to health resources also have minimal or no access

to communicative infrastructures. Acknowledging the role of structural features in organizing communication access and usage, the CCA suggests the important role of addressing the underlying structural features of communication even as policies and programmes are driven towards building communication infrastructures such as information communication technologies (Dutta 2008, 2011).

Individuals, families, and communities respond to structures by enacting their agency. Agency refers to the choices and decisions enacted by individuals, families, and communities in order to negotiate structures. From a communicative standpoint, agency is enacted in the everyday forms of communication that emerge as avenues for expression. Therefore, CCA attends to the role of communication resources as enablers of participation. In the context of new communication technologies and social media, individuals and communities utilize these resources in variety of ways in order to fulfil their needs. Efforts that are grounded in an understanding of local cultures emphasize the role of culture in shaping the technological spaces that are created and fostered through social media (Ali 2011).

In the CCA, structure and agency find meaning in their interaction with culture. Culture refers to the dynamic framework of meanings that offers a guiding framework of actions. Structural features in the environment are understood through the cultural artefacts and symbols that are available to communities. In the backdrop of the existing patterns of disparities in public health outcomes, the interactions among culture, structure, and agency offer avenues for understanding the role of new communication technologies in addressing unequal structures. Furthermore, the CCA offers a framework for understanding the role of scientific information capacity building within grassroots community networks as avenues for facilitating community-involved decision-making. Health communication processes grounded in the CCA underscore the importance of social networks in building health information capacity grounded in scientific information.

Directions for consideration: social media and health

In the conclusion of this chapter, considering the relationship between social media and health raises key questions regarding the role of social media in public health. The directions for consideration include: (1) dynamism, (2) access and usage, (3) participation, (4) literacy, (5) global research on social media, and (6) social media openness and regulation.

Dynamism

New technologies are continually emerging, always shifting, and evolving to address a variety of user needs and motives. For example, new platforms such as Klout have emerged as avenues for integrating Twitter, Facebook, and LinkedIn, offering a Klout rating of a user on the basis of the network strength of the user. Pinterest, Instagram, and Tumblr have emerged as additional social media sites for user participation and collaboration. Also, the rise of YouTube and the newer services such as Pinterest, Instagram, and Tumblr have enabled curating activities as they are organized for image and video sharing.

Access and usage

The Pew Report on Global Technology Uses documents the positive relationship between gross domestic product (GDP) per capita (PPP) and the level of social networking (Pew Research Center 2011). In the Pew Research Center list of countries surveyed, the United States has the highest GDP per capita and also has the highest percentage of adults using social networking sites. Pakistan and India have the lowest GDP per capita and also have the lowest percentage of adults using social networking sites. Education is a key factor in usage of social networking sites (Pew Research Center 2011). Therefore, access and patterns of usage are key components in considering the role of social media in the context of public health. In determining how social media are strategically leveraged in public health campaigns and advocacy efforts, attention needs to be paid to the structural differentials in access to as well as usage of social media (Dutta et al. 2007). Specifically, in interventions with information dissemination components, attention needs to be paid to the potential knowledge gaps that are likely to be generated with the widespread uses of social media without the appropriate consideration of the consequences of these gaps. Across the globe, the widespread diffusion of mobile phones is being leveraged to deliver web-driven content through phones. The fastest growth in mobile phone adoption is taking place in many low-income countries, thus offering opportunities for leveraging mobile phones for delivering web-based resources. Multiple 'mHealth' or mobile health information resources have been launched globally with the goals of reaching out to underserved populations (McNab 2009; United Nations Foundation 2009). Also, specific training programmes have been created with the goal of developing mobile media use capacities for health.

Participation

The user-driven technology of platforms such as Facebook and Twitter enables the participation of community members in the posting and sharing of stories (Thackeray et al. 2008). Users as participants engage in collaborative writing, in the creation of stories and in the sharing of these stories in their social networks. Therefore, essential to social media is their grassroots-driven nature, lending to the social networking technologies that enable user-driven communication within their networks (Thackeray et al. 2013). However, the nature of participation on platforms such as Facebook and Twitter can also be shaped by the broader agendas of public health agencies, marketing departments, policymakers, etc., thus raising important questions about the very nature of participation. To what extent did the solutions originate from within the community of participants as opposed to being imposed by external actors? To what extent is communication in social media contexts truly participatory as opposed to being co-opted within marketing strategies as channels for disseminating top-down information? Future scholarship on social media and public health needs to engage in theoretically understanding the nature of participation on social media and develop appropriate metrics for delineating the various types of participation on social media. Nuanced understandings of participation need to consider the dialogic potential of social media in the backdrop of the co-optive potential of social media as channels for top-down management of health issues. An emphasis on the participatory elements of social media is central to greater citizen participation

in scientific and health-based decision-making processes, turning information into the hands of users and collectives as resources for decision-making through engagement with policymakers and a variety of health services providers.

Literacy

As depicted in the various sections of this chapter, it is not adequate to conceptualize technologies for public health simply in terms of problems of access. Creating access to computers and the Internet is the first step, although there remain multiple additional barriers to the uses of technology (Dutta et al. 2007). These barriers are embedded at the intersections of structure and culture, suggesting that the local cultural needs of underserved communities are often ignored by structures of information communication technologies. As elucidated by the Heart Health Indiana project that was grounded in community-based culturally-centred processes, underserved African American community members resisted the use of technology as a platform for collaboration and instead preferred face-to-face meetings. In spite of specific training programmes and workshops that were directed at building capacities of community members in using technology as a means of collaboration, the community-academic partnership team observed limited uses of technology, especially among low SES community members, resulting in reliance on face-to-face meetings as platforms for collaboration.

Global research on social media

Much of the published research discussed in this chapter suffers from the ethnocentrism of being driven by US-specific research or research available in high-income contexts. What are the ramifications and utilities of social media that fall outside the realm of the typically young, higher-income, educated, English-speaking users of various social media? Whereas much of the digital divide research documents the non-users of specific technologies, more attention needs to be paid to understanding the broader communicative environment of marginalized groups that remain on the outskirts of the landscape of new communication technologies, both in terms of access and also in terms of the variety of communicative barriers that minimize opportunities for participation.

Social media openness and regulation

On the one hand, social media are one of the earliest forms of media that allow two-way participation, bringing two-way dialogue into a mediated context and creating opportunities for wider public participation in shaping policies and programmes. On the other hand, as depicted through the growing research on the public health implications of social media, questions arise regarding the role of policy-based interventions that regulate the usage of social media. Similarly, what are the implications of social-media driven food and sugary drink advertising campaigns that leverage the social media to reach out to the youth? Future research and theorizing needs to engage with questions of values in the context of the regulation of social media with regard to its possible effects on public health.

Conclusion

In conclusion, new communication technologies, specifically social media, intersect with public health issues in complex and dynamic ways. The changing landscape of media consumption

opens up new avenues for audience participation in health-related issues. These various forms of participation constitute a range of functions from information gathering to offering social support to participating in health advocacy. Furthermore, in areas such as food advertising on social media as well as online harassment, attention needs to be paid to the policy-based and intervention frameworks around social media. Finally, public health considerations of social media not only need to attend to the individual level uses of these media forms but also to the broader social and structural patterns within which social media uses are constituted. The emphasis of this chapter was specifically on social media; however, attention also needs to be paid to other forms of technological innovations in healthcare such as electronic health records that may not fall directly under the heading of social media.

Epidemiology: the foundation of public health

Roger Detels

Introduction to epidemiology

Epidemiology is the basic science of public health, because it is the science that describes the relationship of health and/or disease with other health-related factors in human populations, such as human pathogens. Furthermore, epidemiology has been used to generate much of the information required by public health professionals to develop, implement, and evaluate effective intervention programmes for the prevention of disease and promotion of health, such as the eradication of smallpox, the anticipated eradication of polio and guinea worm disease, and the prevention of heart disease and cancer. Unlike pathology, which constitutes a basic area of knowledge, and cardiology, which is the study of a specific organ, epidemiology is a philosophy and methodology that can be applied to learning about and resolving a very broad range of health problems. It is not enough to know what the various study designs and statistical methodologies are. The ‘art’ of epidemiology is knowing when and how to apply the various epidemiological strategies creatively to answer specific health questions.

The uses and limitations of the various epidemiological study designs are presented in this chapter to illustrate and underscore the fact that the successful application of epidemiology requires more than a knowledge of study designs and epidemiological methods. These designs and methods must be applied appropriately, creatively, and innovatively if they are to yield the desired information. The field of epidemiology has been expanding dramatically over the last three decades, as epidemiologists have demonstrated new uses and variations of traditional study designs and methods (Pearce 2012). We can anticipate that the scope of epidemiology will expand even more in the future as increasing numbers of creative epidemiologists develop innovative new strategies and techniques.

The chapters in this section present detailed discussions of the principles and methods of epidemiology. In this introductory chapter, I will attempt to define epidemiology, to present ways in which epidemiology is used in the advancement of public health, and finally, to discuss the range of applications of epidemiological methodologies.

What is epidemiology?

There are many definitions of epidemiology, but every epidemiologist will know exactly what it is that he or she does. Defining

epidemiology is difficult primarily because it does not represent a body of knowledge, as does, for example, anatomy, nor does it target a specific organ system, as does cardiology. Epidemiology is a scientific strategy/method for studying a health problem that can be applied to a wide range of problems, from transmission of an infectious disease agent to the design of a new strategy for healthcare delivery. Furthermore, this methodology is continually changing as it is adapted to a greater range of health problems and more techniques are borrowed and adapted from other disciplines such as mathematics and statistics.

Maxcy, one of the pioneer epidemiologists of the past century, offered the following definition:

Epidemiology is that field of medical science which is concerned with the relationship of various factors and conditions which determine the frequencies and distributions of an infectious process, a disease, or a physiologic state in a human community. (Lilienfeld 1978, p. 88)

The word itself comes from the Greek *epi*, *demos*, and *logos*; literally translated, it means the study (*logos*) of what is upon (*epi*) the people (*demos*). John Last, in the *Dictionary of Epidemiology* (Last 2001), has defined epidemiology as follows:

The study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems.

Last’s definition underscores that epidemiologists are concerned not only with disease but also with ‘health-related events’, and that ultimately epidemiology is committed to control of disease. All epidemiologists, however, will agree that epidemiology concerns itself with populations rather than individuals, thereby separating it from the rest of medicine and constituting the basic science of public health. Following from this, therefore, is the need to describe health and disease in terms of frequencies and distributions in the population. The epidemiologist relates these frequencies and distributions of specific health parameters to the frequencies of other factors to which populations are exposed in order to identify those that may be causes of ill health or promoters of good health. Inherent in the philosophy of epidemiology is the idea that ill health is not randomly distributed in populations, and that elucidating the reasons for this non-random distribution will provide clues regarding the risk factors for disease and the biological mechanisms that result in loss of health.

Because epidemiology usually focuses on health in *human* populations, it is rarely able to provide experimental proof in the

sense of Koch's postulates, as can often be done in the laboratory sciences. Epidemiology more often provides an accumulation of increasingly convincing indirect evidence of a relationship between health or disease and other factors. This process, referred to as causal inference (see Chapter 5.14), includes considering an observed relationship in terms of its strength, consistency, specificity, temporality, biological gradient, plausibility, coherence, and experimental evidence (Hill 1965).

Although they will differ on the exact definitions of epidemiology, most epidemiologists will agree that they try to characterize the relationships among the *agent*, the *environment*, and the *host* (usually human). The epidemiologist considers health to represent a balance among these three forces, as shown in Fig. 5.1.1.

Changes in any one of these three factors may result in loss of health. For example, the host may be compromised as a result of treatment with steroids, making him or her more susceptible to agents that do not ordinarily cause disease. On the other hand, a breakdown in the water supply system may result in an increased exposure of people to agents such as cryptosporidium, as happened in 1993 in Milwaukee, Wisconsin (MacKenzie et al. 1994). Finally, some agents may become more or less virulent over time—often because of the promiscuous use of antibiotics—thereby disturbing the dynamic balance among agent, host, and environment. Two examples are the cases of acute necrotizing fasciitis caused by group A streptococcus (Communicable Disease Surveillance Centre 1994) and the development of multidrug-resistant tuberculosis (Chapman and Henderson 1994).

The epidemiologist uses another triad to study the relationship of agent, host, and environment: *time–place–person*. Using various epidemiological techniques, described in subsequent chapters, the epidemiologist describes disease or disease factors occurring in the population in terms of the characteristics of time (e.g. trends, outbreaks, etc.), place (the geographic area in which the disease is occurring), and person (the characteristics of the affected individuals; e.g. age, gender, etc.) to elucidate the causative agent, the natural history of the disease, and the environmental factors that increase the likelihood of the host acquiring the disease. With this information, the epidemiologist is able to suggest ways to intervene in the disease process to prevent either disease or death.

Epidemiology has been described as the 'art of the possible'. Because epidemiologists work with human populations, they are rarely able to manipulate events or the environment as can the laboratory scientist. They must, therefore, exploit situations as they exist naturally to advance knowledge. They must be both pragmatic and realistic; they must realize both the capabilities and limitations of the discipline. Morris has said that the 'epidemiologic method is the only way to ask some questions. . . , one way of asking others and no way at all to ask many' (Morris 1975, p. 96). The art of epidemiology is to know both when epidemiology is the method of choice and when it is not, and how to use it to answer the question.

Health is a state of equilibrium between:

Fig. 5.1.1 The dynamic relationship between agent, host, and environment in epidemiology.

Applying the epidemiological method to resolve a health question successfully can be compared to constructing a memorable Chinese banquet. It is not enough to have the best ingredients and to know the various Chinese cooking methods. The truly great chefs must be able to select the appropriate ingredients and cooking methods to bring out the flavours of each dish, and further, must know how to construct the correct sequence of dishes to excite the palate without overwhelming it. They create a memorable banquet by adding their creative genius to the raw ingredients and the established cooking methods. Similarly, it is not enough for the epidemiologist to know the various strategies and methods of epidemiology; the innovative epidemiologist must be able to apply them creatively to obtain the information needed to understand the natural history of the disease. It is not enough to know what a cohort study is; the epidemiologist must know when the cohort design is the appropriate design for the question at hand, and then must apply that design appropriately and creatively. These skills make epidemiology more than a methodology. It is this opportunity for creativity and innovation that provides excitement for the practitioner and makes the successful practice of epidemiology an art.

For example, Imagawa et al. (1989) identified probable transient HIV-1 infection in men, implying clearance of the virus by the immune system of the men, by focusing their viral isolation studies on the relatively few HIV-1-antibody-negative homosexual men who had many different sexual partners; a simple cohort study of antibody-negative individuals would have required a cohort of thousands of men rather than the 133 studied. The effects of passive smoking were demonstrated by cohort studies of non-smoking family members of smokers and in nursing students by comparing the reported symptoms in room-mates of smokers and non-smokers who kept diaries of their symptoms: the room-mates of the smokers had a 1.8 greater risk of episodes of phlegm than room-mates of non-smokers (Colley et al. 1974; Tager et al. 1979; Schwartz and Zeger 1990). Tashkin et al. (1984) demonstrated that children of smokers had lower levels of lung function than children of non-smokers. All of these investigators used traditional study designs, but demonstrated their creativity by applying that design to those specific populations which were most likely to reveal a relationship if it existed.

Epidemiological studies rarely provide 'proof' of a causal relationship. Thus, there is continuing debate among epidemiologists about what constitutes adequate criteria for inferring a causal relationship from epidemiological studies (Rothman 1988). Hill (1965) suggested the following minimum criteria for establishing a causal relationship between exposure and consequence/outcome: strength of association (statistical probability and risk ratio), consistency of findings across multiple studies, specificity of the relationship, temporality (outcome follows causation not heuristic), biological gradient (a dose–response relationship), plausibility, coherence (consistency with prior knowledge), experimental evidence, and analogy (relationship hypothesized is similar to that in known relationships). Susser has added to these criteria the ability of the observed relationship to correctly predict other relationships (Rothman 1988). Rothman and Greenland define a cause as 'an event, condition or characteristic that preceded the disease onset and that, if the event, condition or characteristic has been different in a specified way, the disease would not have occurred at all or would not have occurred until sometime

later' (Rothman and Greenland 1998, p. 8). The sufficient component cause model defined a sufficient cause as 'a complete causal mechanism' that inevitably produces disease (Rothman and Greenland 1998, p. 8). A minimal set of factors results in an outcome, that is, each factor in a sufficient cause is a component cause and most 'causes' that are the 'causes of interest' in studies are component causes of a sufficient cause, for example, HIV infection can only occur following exposure to the HIV virus (sufficient cause). The exposure to the virus occurs through component causes (unprotected heterosexual intercourse, intravenous drug use). Therefore, a sufficient cause is a minimal set of factors that will cause the outcome. The debate goes on, but the principle is the same: epidemiological studies seldom provide 'proof' of a causal relationship in the sense of Koch's postulates, but may be used to reveal a possible relationship and build a convincing case that this relationship is causal. However, the presence of a relationship does not imply a causal relationship and the 'art' of causal inference assists in distinguishing causal from non-causal relationships (Aschengrau and Seage 2008).

More recently there is increased recognition that disease is not a product of individual circumstances at a given point of time, but rather a product of circumstances over a life course, possibly beginning *in utero* and continuing during a life course (Galea et al. 2010). This includes the complex interactions over time that result in a dynamic up- or down-regulation of different factors that closely approximates the temporal nature of causality (Galea et al. 2010).

Uses of epidemiology in support of public health

Epidemiology is the basic science of public health because it is the health science that describes health and disease associations in *populations* rather than in individuals, information essential for the formulation of effective public health initiatives to prevent disease and promote health in the community. I have taken the liberty of updating the 'Functions of Epidemiology', first expounded by Morris (1957) and Holland et al. (2007). They are as follows:

1. *Describe the spectrum of the disease:* disease represents the end point of a process of alteration of the host's biological systems. Although many disease agents are limited in the range of alterations they can initiate, others, such as measles, can cause a variety of disease end points. For example, the majority of infections with rubeola (measles) virus result in the classical febrile, blotchy-rash disease, but the rubeola virus can also cause generalized haemorrhagic rash and acute encephalitis. Years after initial infection, rubeola can also cause subacute sclerosing panencephalitis (SSPE), a fatal disease of the central nervous system.

Various types of epidemiological studies have been used to elucidate the spectrum of disease resulting from many agents and conditions; for example, cohort studies have been used to document the role of high blood pressure as a major cause of stroke, myocardial infarct, and chronic kidney disease. For rare diseases such as SSPE and multiple sclerosis, case-control studies have been useful to identify the role of the rubeola virus (Detels et al. 1973; Alter 1976). Knowing the spectrum of disease that can result from specific infections and conditions allows the public health professional to design more effective intervention strategies; for example, education, screening, and

treatment programmes to reduce the prevalence of high blood pressure will also reduce the incidence of myocardial infarct, stroke, and chronic kidney disease (Hypertension Detection and Follow-up Program Cooperative Group 1979).

2. *Describe the natural history of disease:* epidemiological studies can be used to describe the natural history of disease, to elucidate the specific alterations in the biological system in the host, and to improve diagnostic accuracy. For example, cohort studies of individuals who were infected with HIV, the 'AIDS virus', revealed that a drop in the level of T lymphocytes having the CD4 marker was associated with being infected with HIV (Polk et al. 1987), and that a further decline in CD4 cells was associated with developing clinical symptoms and AIDS (Detels et al. 1987). This observation stimulated immunologists to focus their research on the interaction of the immune system and HIV. From a clinical perspective, clinicians can target HIV-antibody-positive individuals who have declining CD4 cells for viral suppressive or antiretroviral treatment when it is clinically indicated. Epidemiology can also be used to describe the impact of treatment on the natural history of disease. For example, a cohort study design was used to demonstrate the public health effectiveness of combined highly active antiretroviral therapy on reducing the incidence of AIDS and extending survival of those who already had the disease (Detels et al. 1998). Thus, describing the natural history of AIDS among both treated and untreated individuals has assisted researchers to focus their studies and clinicians to use the limited treatment modalities available more effectively (Phair et al. 1992). The field of 'clinical epidemiology' applies research on the natural history of disease to improving the diagnostic accuracy of physicians in their clinical practice (Sackett et al. 1991).

3. *Community diagnosis:* epidemiological surveys are often used to establish the morbidity and mortality from specific diseases, allowing efficient use of limited public health funds for control of those diseases having the greatest negative impact on the health of the community. For example, an epidemiological survey in one area of China identified the epidemic of HIV due to plasma donations in villages (Wu and Detels 1995; Wu et al. 2001; Ji et al. 2006). The use of disability-adjusted life years (DALYs) has allowed quantification of the importance of non-lethal conditions on the public's health (Murray 1994).

4. *Describe the clinical picture of a disease:* epidemiological strategies can identify who is likely to get a disease such as capillariasis, the characteristic symptoms and signs, the extent of the epidemic, the risk factors, and the causative agent, and can help to determine the effectiveness of treatment and control efforts (Detels et al. 1969b).

5. *Identify factors that increase or decrease the risk of acquiring disease:* having specific characteristics increases the probability that individuals will or will not develop disease. These 'risk factors' may be social (smoking, drinking), genetic (ethnicity), dietary (saturated fats, vitamin deficiencies), and so on. Knowing these risk factors can often provide public health professionals with the necessary tools to design effective programmes to intervene before disease occurs. For example, descriptive, cross-sectional, case-control, cohort, and intervention studies have all shown that smoking is the biggest single risk factor for ill health, because

it is a major risk factor for cardiovascular disease, chronic respiratory disease, and many cancers (e.g. of the lung, nasopharynx, and bladder). Thus, smoking is the leading cause of disability and death in developed countries, if not the world. Health education campaigns and other strategies to stop or reduce smoking, based on these epidemiological studies, are now a major public health activity in most countries of the world.

6. *Identify precursors of disease and syndromes*: high blood pressure, a treatable condition, has been identified through case-control and cohort studies as a precursor to heart disease, stroke, and kidney disease (Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure 1997).
7. *Test the efficacy of intervention strategies*: a primary objective of public health is to prevent disease through intervention in the disease process. But a vaccine or other intervention programme must be proven effective and safe before it is used in the community. Double-blind placebo-controlled trials are a necessary step in developing an intervention programme, whether that programme is administration of a new vaccine, a behavioural intervention strategy to stop smoking, or a community intervention study to lower heart disease. Although it may be argued that injection of a saline placebo is no longer considered ethical, a proven vaccine, such as polio, can often be used as a placebo for a trial of a new vaccine for a different disease, as was used for trials of rubella vaccines in Taiwan (Detels et al. 1969a). Widespread use of an intervention not subjected to epidemiological studies of efficacy may result in implementation of an ineffective intervention programme at great public expense, and may actually result in greater morbidity and mortality because of an increased reliance on the favoured but unproven intervention and a reduced use of other strategies that are thought to be less effective but which are actually more effective.

Although an intervention such as a vaccine may have been demonstrated to have efficacy in double-blind trials, it may fail to provide protection when used in the community. Double-blind trials may demonstrate the 'biological efficacy' of the vaccine; but if the vaccine is not acceptable to the majority of the public, they will refuse to be vaccinated, and the 'public health effectiveness' of the vaccine will be very low. For example, the typhoid vaccine provided some protection against small infecting inocula, but the frequency of unpleasant side effects with the whole-cell vaccines and the need for multiple injections in the past influenced many people against being vaccinated (Chin 2000).

Another problem of inferring public health efficacy from small vaccine trials is that volunteers for these trials may not be representative of the general public, which needs to be protected against a specific disease. Thus, broad-based intervention trials also need to be carried out, to demonstrate the acceptability and public health effectiveness of a vaccine or other intervention to the entire population in need of protection.

As there are adverse effects associated with any vaccine, ongoing evaluations of the cost-benefit relationship of specific vaccines are important. By comparing the incidence of smallpox with the incidence of adverse effects from the smallpox vaccine, Lane et al. (1969) demonstrated that more disease resulted from routine use of the vaccine in the United States than by transmission from imported cases.

There are several epidemiological strategies that can be used for ongoing evaluation of intervention programmes. Serial cross-sectional studies can be used to determine if there has been a change in the prevalence of disease or of indicators of health status over time. The cohort design can be used to compare incidence of disease in comparable populations receiving and not receiving the prevention programme. The case-control design can be used to determine if there are differences in the proportion of cases and non-cases who received the intervention programme.

8. *Investigate epidemics of unknown aetiology*: epidemiological strategies were used to establish the extent, cause, modes of transmission, and risk factors for Ebola haemorrhagic fever, which first occurred in the Congo in 1976 (Feldmann et al. 1996; King 2013), and capillariasis in the Philippines in the mid 1960s (Detels et al. 1969b).
9. *Evaluate public health programmes*: departments of health are engaged in a variety of activities to promote the health of the community, ranging from surveillance and vaccination programmes to clinics for the treatment of specific diseases. Ongoing evaluation of such programmes is necessary to ensure that they continue to be cost-effective. Periodic review of routinely collected health statistics can provide information about the effectiveness of many programmes. For programmes for which relevant statistics are not routinely available, cohort studies and serial cross-sectional studies of the incidence and changing prevalence of the targeted disease in the populations which are the intended recipients of these programmes can measure whether the programmes have had an impact and are cost-effective. For example, most countries have established sexually transmitted infections (STI) clinics, but studies in Thailand (Prempreet et al. 2007) and Beijing (Zhao et al. 2007) have demonstrated that the majority of the patients with STIs do not attend the government STI clinics.
10. *Elucidate mechanisms of disease transmission*: understanding the mechanisms of disease transmission can suggest ways in which public health professionals can protect the public by stopping transmission of the disease agent. Epidemiological studies of the various arboviral encephalitides have incriminated certain species of mosquitoes as the vectors of disease and specific animals as the reservoirs for the viruses. For example, public health efforts in California to prevent western equine encephalitis have concentrated on control of the mosquito vector and vaccination of horses, which are a reservoir of the virus. Although an effective vaccine for smallpox had been available for almost 200 years, eradication of the disease was not achieved until the recognition that the low infectivity of varicella virus and the relatively long incubation for development of smallpox could be used to develop a strategy of surveillance for cases, with identification and immediate vaccination of all susceptible contacts (containment). Using this containment strategy based on epidemiological principles, smallpox was eradicated through a worldwide effort in less than 10 years (Fenner et al. 1988).
11. *Elucidate the molecular and genetic determinants of disease progression*: epidemiological strategies helped to elucidate the changes in the human immune response by CD4 and CD8

cells that accompany infection and disease progression by disease agents (Detels et al. 1983; Fahey et al. 1984; Ho et al. 1995), and genetic factors (such as CCR5 absence or heterozygosity) that prevent HIV infection and slow progression of HIV disease (Liu et al. 2004).

12. *Implementation science*: recently the scientific community and policymakers have recognized the slow rate at which scientific advances are translated into public health policies and medical and public health practice. Thus, there is growing support for identifying and testing strategies that will speed up the process of translating science into action and practice. Epidemiological methods will play an important role in identifying and testing these strategies.

From the examples given in the preceding list, it should be clear that epidemiology functions as the backbone or core of evidence-based public health practices, as well as a key strategy for evaluating the effectiveness of both clinical and public health interventions. As such it is a particularly pertinent instrument for evidence-based policy formulation as well as a tool for building advocacy and resource justification for rational policies and programmes.

Applications of epidemiology

Specific epidemiological study designs are used to achieve specific public health goals. These goals range from identifying a suspected exposure–disease relationship to establishing that relationship, to designing an intervention to prevent it, and finally, to assessing the effectiveness of that intervention. The usual sequence of study designs in the identification and resolution of a disease problem is as follows:

- ◆ Ecological studies
- ◆ Cross-sectional (prevalence) surveys
- ◆ Case–control studies
- ◆ Cohort studies
- ◆ Experimental studies
- ◆ Adaptive trial design.

There are, however, many exceptions to the application of this sequence of study designs, depending on such factors as the prevalence and virulence of the agent and the nature of the human response to the agent.

The earliest suspicion that a relationship exists between a disease and a possible causative factor is frequently obtained by observing correlations between exposure and disease from existing data such as mortality statistics and surveys of personal or national characteristics. These can be correlations observed across geographical areas (ecological studies) or over time, or a combination of both. Many of the initial epidemiological investigations on chronic bronchitis used vital statistics data, particularly data on mortality. Case–control studies identified smoking as a possible causal factor for chronic bronchitis. Subsequent cohort studies confirmed the relationship. A decline in respiratory symptoms of chronic bronchitis and a concurrent but slower decline in lung function have been observed in individuals who cease smoking (Colley 1991). Using the information obtained from these studies,

public health has implemented vigorous antismoking campaigns and has used epidemiology to assess their effectiveness.

Although this is the usual sequence in which the various epidemiological study designs are applied, there are exceptions to this sequence. Furthermore, all study designs are not appropriate to answer all health questions. The usual applications of each of the epidemiological study designs and their limitations are, therefore, presented briefly in this subsection and in greater depth in subsequent chapters.

Ecological studies

The use of existing statistics to correlate the prevalence or incidence of disease in groups or populations to the frequency or trends over time of suspected causal factors in specific localities has often provided the first clues that a particular factor may cause a specific disease. These epidemiological strategies, however, document only the co-occurrence of disease and other factors in a population; the risk factors and the disease may not be occurring in the same people within the population. These types of descriptive studies are inexpensive and relatively easy to perform, but the co-occurrence observed may be merely due to chance. For example, the incidence of both heart disease and lung cancer has increased concurrently with the increased use of automatic washing machines in the United States. Few people, however, would attribute the increase in these two diseases to the use of automatic washing machines. Thus, ecological studies must be interpreted with caution. Nonetheless, they often reveal important relationships and can provide a strong rationale for undertaking more expensive analytic studies (see Chapter 5.2).

Cross-sectional/prevalence surveys

Cross-sectional/prevalence surveys establish the frequency of disease and other factors in a community. Because they require the collection of data, however, they can be expensive. They are useful to estimate the number of people in a population who have disease and can also identify the difference in frequency of disease in different subpopulations. This descriptive information is particularly useful to health administrators who are responsible for developing appropriate and effective public health programmes.

Cross-sectional studies can also be used to document the co-occurrence of disease and suspected risk factors not only in the population but also in specific individuals within the population. The cross-sectional study design is useful to study chronic diseases such as multiple sclerosis, which has a reasonably high prevalence, but an incidence that is too low to make a cohort study feasible (Detels et al. 1978). On the other hand, they are not useful for studying diseases that have a very low prevalence, such as SSPE or variant Creutzfeldt–Jakob disease. Cross-sectional studies are subject to problems of respondent bias, recall bias, and undocumented confounders. Further, unless historical information is obtained from all the individuals surveyed, the time-relationship between the factor and the disease is not known. Also, prevalence surveys identify people who have survived to that time point with disease, and thus, under-represent people with a short course of disease.

The cross-sectional study design is used in two special types of studies: field studies and surveillance. Field studies are usually investigations of acute outbreaks, which require immediate identification of the causative factors if effective public

health interventions are to be implemented in a timely fashion. Surveillance is the monitoring of disease- or health-related factors over time and uses serial cross-sectional surveys to observe trends. Surveillance is important to identify diseases that are becoming an increasing public health problem, to assure that diseases already brought under control remain under control, and to evaluate the impact of public health intervention strategies (see Chapters 5.3, 5.4, and 5.17).

Case-control studies

The case-control study compares the prevalence of suspected causal factors between individuals with disease and controls who do not have the disease. If the prevalence of the factor is significantly different in cases than it is in controls, this factor may be associated with the disease. Although case-control studies can identify associations, they do not measure risk. An estimate of relative risk, however, can be derived by calculating the odds ratio. Case-control studies are often the analytic study design used initially to investigate a suspected association. Compared to cohort and experimental studies, they are usually relatively cheap and easy to perform. Cases can often be selected from hospital patients and controls either from hospitalized patients with other diseases or by using algorithms or formulas for selecting community (neighbourhood) or other types of controls. Selection bias, however, is often a problem, especially when using either hospitalized cases or controls. The participants are seen only once, and no follow-up is necessary. Although time sequences can often be established retrospectively for factors elicited by interview, they usually cannot be for laboratory test results. For example, an elevation in factor B may either be causally related, or it may be a result of the disease process and not a cause. Furthermore, factors elicited from interview are subject to recall bias; for example, patients are often better motivated to recall events than controls because they are concerned about their disease.

The case-control study is particularly useful for exploring relationships noted in observational studies. A hypothesis, however, is necessary for case-control studies. Relationships will be observed only for those factors studied. Case-control studies are not useful for determining the spectrum of health outcomes resulting from specific exposures, because a definition of a case is required in order to do a case-control study. On the other hand, these studies are the method of choice for studying rare diseases, and are often indicated when a specific health question needs to be answered quickly (see Chapter 5.5).

Cohort studies

Cohort studies follow defined groups of people without disease to identify risk factors associated with disease occurrence. They have the advantage of establishing the temporal relationship between an exposure and a health outcome, and thus measure risk directly. Because the population studied is often defined on the basis of its known likelihood of exposure to suspected factors, cohort studies are particularly suitable for investigating health hazards associated with environmental or occupational exposures. Further, these studies will measure more than one outcome of a given exposure, and therefore, are useful for defining the spectrum of disease resulting from exposure to a given factor. Occasionally, a cohort study is done to elucidate the natural history of a disease when a group that has a high incidence of disease, but in which specific

risk factors not previously known, can be identified. Although this cohort is not defined based on a known exposure, questions are asked and biological specimens are collected from which exposure variables can be identified concurrently or in the future.

Unfortunately, cohort studies are both expensive and time consuming. Unless the investigator can define a cohort in which risk factors were measured at some time in the past and has the assurance that the cohort has been completely followed up for disease outcomes in the interim (historical cohort), this design can take years to decades to yield information about the risks of disease resulting from exposure to specific factors. Ensuring that participants remain in a cohort study for such long periods of time is both difficult and expensive. Further, the impact of those who drop out of follow-up must be taken into account in the analysis and interpretation of these studies. Finally, exposures may vary over time, complicating the analysis of their impact.

Because of the cost and complexity of cohort studies, they are usually done only after descriptive, cross-sectional, and/or case-control studies have suggested a causal relationship. The size of the cohort to be studied is dependent, in part, on the anticipated incidence of the disease resulting from the exposure. For diseases with a very low incidence, population-based cohort studies are usually not feasible, either in terms of the logistics or of the expense of following very large numbers of people, or both. Cohort studies establish the risk of disease associated with exposure to a factor, but do not 'prove' that the factor is causal; the observed factor may merely be very closely correlated with the real causative factor or may even be related to the participants' choice to be exposed.

A variant of the cohort study that has become popular is the 'nested case-control study' (Gange et al. 1997). Cases arising from a cohort study are compared with individuals followed in the cohort who have not developed disease using the usual case-control analytic strategies. The advantage of this type of study is that the exposure variables are collected before knowledge of the outcome, and therefore, are unlikely to be tainted by recall bias (see Chapter 5.6).

Experimental studies

Experimental studies differ from cohort studies because it is the investigator who makes the decision about who will be exposed to the factor based on the specific design factors to be employed (e.g. randomization, matching, etc.). Therefore, confounding factors such as choice that may have led to the subjects being exposed in the cohort studies are usually not a problem in experimental studies. Because epidemiologists usually study human populations, there are few opportunities for an investigator to deliberately expose participants to a suspected factor. On the other hand, intervention studies of randomly assigned individuals (see Chapter 5.7) or communities (see Chapters 5.8–5.10) to receive or not receive an intervention programme that demonstrates a subsequent reduction in a specific health outcome in the intervention group do provide strong evidence, if not proof, of a causal relationship. Because of the serious implications of applying an intervention that may alter the biological status of an individual or the sociopolitical behaviour of a community, intervention studies should not be undertaken until the probability of a causal or risk relationship has been well established using the other types of study designs. A randomized clinical trial or vaccine trial is a typical example of an experimental study (see Chapters 5.7–5.10).

Meta-analysis

Because individual epidemiological studies rarely provide proof of causation and results of different studies can vary for a number of reasons, including small sample size, a recent trend has been to combine similar studies to increase the power of the analysis. This strategy for data synthesis is known as *meta-analysis*. It has been especially helpful in studying diseases with a low incidence or where similar studies have given conflicting results. But meta-analysis can yield opposite conclusions, especially if different sets of studies are used in the analysis. Meta-analysis investigates and identifies all available studies both quantitatively and qualitatively. The qualitative analysis excludes poor-quality studies that may be considered flawed by the investigators (Aschengrau and Seage 2008). As a result, meta-analysis is prone to heterogeneity problems as different case definitions and different sources of controls cannot be adjusted for in the analysis (Rothman et al. 2008) (see Chapter 5.15).

Adaptive trial designs

Adaptive trial designs provide a way to address uncertainty about choices made during the planning of a study and allow for planned modifications after initiation of the study at pre-specified time points or end points as data is accumulated within a study (Kairalla et al. 2012). This design provides flexibility and efficiency (smaller sample size) of study designs and increases the likelihood of a 'successful' trial that will yield the outcome of interest. However, improper adaptations can result in study bias. This type of study design can be applied in comparative effectiveness studies (Kairalla et al. 2012).

Methodological issues

Epidemiological studies, because they deal with humans, are subject to problems such as bias (deviation of results from truth), due to the strategies of recruiting participants or to differential recall among persons with and without disease, and confounding, due to factors which are associated with both the exposure variables and outcome variable under study. A cause may combine with another cause to produce an outcome (Susser et al. 2006). For example, a genetic abnormality can be modified by prenatal exposures, resulting in an adverse outcome (e.g. autism). This process is called interaction or effect modification and attempts are made to capture these with statistical measures (Susser et al. 2006). In the last several decades, many new techniques have been developed to reduce the effect of these factors, which can influence the outcome of a study and, in some instances, can cause apparent relationships to be observed which are in fact false (see Chapters 5.12 and 5.13).

Summary

Epidemiology is the core science of public health because it defines health and disease in human populations, describes disease aetiology, and evaluates public health control efforts. It achieves these goals through a variety of strategies and methods. Epidemiology is a dynamic science that is continually evolving new strategies and methods in support of public health goals.

Ecological variables, ecological studies, and multilevel studies in public health research

Ana V. Diez Roux

Introduction to ecological variables and ecological studies

There has been much discussion in epidemiology about the utility of ecological variables and ecological studies. Most of these discussions centre on the limitations of ecological studies in drawing inferences regarding the relations between individual-level variables. These limitations are due to the presence of the ecological fallacy, that is, the well-established logical fallacy inherent in making inferences regarding individual-level associations based on group-level data (Piantadosi et al. 1988; Greenland 1992; Morgenstern 1995). Because of these limitations it is often argued that ecological studies should be limited to ‘hypothesis generation’, leaving the more esteemed process of ‘hypothesis testing’ to individual-level data.

A key notion that has received much attention in epidemiology over the last decade is that not all disease determinants can be conceptualized as individual-level attributes, hence the need to consider features of the groups to which individuals belong when studying the causes of ill health. This led epidemiologists and public health researchers to rethink the ideas on ecological studies and ecological variables traditionally espoused in epidemiology (Von Korff et al. 1992; Schwartz 1994; Susser 1994a, 1994b; Diez-Roux 1998; Blakely and Woodward 2000; Macintyre and Ellaway 2000; Diez Roux 2004; Subramanian et al. 2009). It has been recognized, and is now generally accepted, that constructs defined at the levels of groups or aggregates may be relevant to health. This has motivated researchers to consider the ways in which these group-level constructs can be examined in epidemiological studies. The characterization of group-level constructs often necessitates the use of group-level (or ecological) variables. In this chapter, the terms group-level or ecological will be used interchangeably to refer to variables that characterize groups. These variables can provide information that is not captured by individual-level variables. In addition, the desire to investigate the causal effects of group-level constructs on health has implications for study design and analysis. The interest in the investigation of how group-level constructs

may affect health has been manifested, for example, in research and debate on the possible health effects of income inequality (Lynch et al. 2003; Subramanian and Kawachi 2003), social capital (Kawachi et al. 1999; Lynch et al. 2000), and neighbourhood characteristics (Pickett and Pearl 2001; Diez Roux 2004, 2007; Oakes 2004; Subramanian 2004). The renewed interest in the ‘ecological’, ‘macro’, or ‘group-level’ determinants of health occurred within a broader recognition of the need to consider multiple levels of organization (e.g. from molecules to society) in studying the determinants of health and disease.

The conceptual and analytical issues that arise when considering the uses of ecological studies and ecological variables derive from the presence of multiple levels of organization and nested data structures more generally. For example, many problems that arise when dealing with individuals nested within groups (e.g. persons nested within geographical areas), are also present when dealing with groups nested within larger groups (e.g. states nested within countries), persons nested within families, or multiple measurements on individuals over time (in this case the ‘group’ is the individual, and the ‘individuals’ are the measurement occasions). The need to deal with multiple levels of organization is the norm rather than the exception in epidemiology.

The presence of multiple levels has two important implications. First, the units of analysis (or observations for which independent and dependent variables are measured) can be defined at different levels. The unit of analysis determines the level at which variability is examined. For example, a study with individuals as the units of analysis (i.e. where each observation is an individual) can investigate the causes of interindividual variation in the outcome. A study with groups as the units of analysis (where observations are groups) can investigate the causes of intergroup variation in the outcome. A study involving repeated measures on individuals over time in which measures at different points in time are the units of analysis can investigate the causes of variability across measures. As we will see, the use of units of analysis at one level to make inferences about the causes of variability at a different level leads to a series of methodological problems.

The second implication of the presence of multiple levels is that constructs relevant to health can be conceptualized (and measured) at different levels. Constructs pertaining to a higher level may be important in understanding variability at a lower level, and, conversely, constructs defined at a lower level may be important in understanding variability at a higher level. For example, characteristics of the groups to which individuals belong may be important in explaining interindividual variability, and characteristics of the individuals composing the groups may be important in explaining intergroup variability. Analogously, when investigating multiple measures on individuals over time, individual characteristics may be important in understanding variability across measures, and factors specific to measurement occasions may be important in understanding variability across individuals.

This chapter discusses the use of ecological variables, ecological studies, individual-level and multilevel studies in epidemiology within the broader context of the implications of multiple levels of organization for understanding disease aetiology. Although the discussion will focus on the simple case of individuals nested within groups, it is generalizable to many other situations involving nested data structures, as noted earlier. The first section reviews the classic distinction between ecological and individual-level studies made in epidemiology and provides historical examples of the use of ecological studies in public health. The second section summarizes the sources of the ‘ecological fallacy’, placing this fallacy within the context of other fallacies that may arise when the presence of multiple levels is ignored. The third section discusses types of group-level or ecological variables and revisits the full range of possible study designs based on: (1) the units of analysis (and the level at which variability is examined) and (2) the levels at which relevant constructs are defined and measured. The final section highlights some challenges faced by epidemiology when it investigates the multilevel determinants of health.

Ecological studies and their use in public health

Epidemiology has traditionally distinguished two types of studies based on the units of analysis: ecological studies and studies of individuals. Ecological studies are studies in which groups are the units of analysis: both the dependent and the independent variables are measured for groups, and intergroup variability (and associations between independent and dependent variables across groups) is examined. For example, common ecological studies in public health involve measuring rates of disease for different geographic areas, and relating these rates to area social or physical characteristics (e.g. measures of area median income; levels of air pollution, water hardness, and radiation). Ecological studies are often cross-sectional with independent and dependent variables measured at the same point in time. However, ecological studies can also involve repeated measures on a group, or on several groups, over time, as in time-trend studies (Susser 1994a, 1994b; Morgenstern 1995). For example, an ecological study could examine yearly incidence rates of disease for different regions over a 10-year period and investigate the relation of these incidence rates to area characteristics that do and do not change over time. Ecological studies can also involve the analysis of groups randomized to receive or not receive an intervention. In many ecological studies the predominant analytic approach involves

the estimation of correlation coefficients between the group-level exposure and the group-level outcome. However, many other analytic approaches are also possible, including the estimation of other measures of association (such as rate differences or rate ratios) using linear or log-linear models (Morgenstern 1995).

In contrast, in individual-level studies the units of analysis are individuals: both independent and dependent variables are measured for individuals and interindividual variation (and associations between independent and dependent variables across individuals) are investigated. Based on their design, individual-level studies can be cross-sectional (when both independent and dependent variables are measured at the same point in time), cohort (when individuals are followed over time to compare risk of the outcome in exposed and unexposed people), or case-control (when a sample of people with the outcome is compared with a sample of controls with regard to the presence of certain exposures).

Because the units of analysis differ in ecological and individual-level studies, the information they provide (and the information they lack) also differs. Ecological studies include information on group characteristics (which may sometimes be simply summaries of the characteristics of individuals in the group), but lack information on the cross-classification of individual-level characteristics within groups. For example, an ecological study may relate the percentage of smokers in different groups to mortality rates, but has no information on whether within groups, smokers were actually the ones more likely to die. On the other hand, individual-level studies focus on interindividual variation, and have information on individual-level characteristics but often lack information on characteristics of the groups to which individuals belong. Although the omission of relevant group-level characteristics in individual-level studies is rarely recognized as a problem, it also can lead to incorrect inferences, as will be discussed in more detail in the sections that follow.

Uses of ecological studies in public health

Descriptive ecological studies in which rates of disease or death are compared over time or across geographic areas have been a staple of epidemiology for centuries. Chadwick used an ecological approach in his famous *Report on an Inquiry into the Sanitary Condition of the Labouring Population of Great Britain* in 1842 (Chadwick 1965). Table 5.2.1 shows a portion of Chadwick’s report,

Table 5.2.1 Death rates compared in three successive decades in a drained and an undrained town

The following has been the proportion of deaths to the population in the two towns:		
	Beccles	Bungay
Between the years 1811 and 1821	1 in 67	1 in 69
Between the years 1821 and 1831	1 in 72	1 in 67
Between the years 1831 and 1841	1 in 71	1 in 59

You will therefore see that the rate of mortality has gradually diminished in Beccles since it has been drained, whilst Bungay, notwithstanding its larger proportion of rural population, it has considerably increased.

in which mortality for a drained area is compared to mortality for an undrained area at three parallel points in time. By comparing mortality rates over time in both communities (one drained and the other undrained), he was able to draw inferences regarding the relationship between drainage and ill health. Drainage was the 'exposure', mortality the outcome, and communities the units of analysis. With these findings Chadwick had grounds to institute a system of sanitation nationwide. Although the miasmatic theory of disease causation which Chadwick espoused (and which he believed was supported by his data) was later shown to be mistaken, the method of sanitation that Chadwick introduced was probably as important as any other single measure in modern times (Susser 1973).

Early in his studies, John Snow also used an ecological approach in comparing cholera rates for London districts, and examining whether differences in these rates were related to differences in the sources of water (Susser 1973) (Table 5.2.2). The units of analysis were districts, and both the independent variable (source

of water) and the dependent variable (cholera rates) were measured at the district level. At the beginning of the twentieth century, Goldberger and colleagues (Goldberger et al. 1920; Terris 1964) used an ecological approach to compare incidence rates of pellagra across villages. Their findings linking food availability at the village level to village pellagra rates contributed to the demonstration that pellagra was not an infectious disease, as was believed by many at the time.

More recently, ecological studies relating rates of cardiovascular disease across countries to risk factor prevalences (Ancel Keys's Seven Country Study) laid the foundation for future work on the epidemiology and causes of cardiovascular disease (Keys 1980). For example, data from the Seven Countries Study showed a relationship between the average proportion of calories derived from saturated fat and coronary heart disease mortality. Another recent example is provided by psychiatric epidemiology. Ecological studies have demonstrated that the incidence of acute transient psychoses varies dramatically across sociocultural

Table 5.2.2 Showing the mortality from cholera, and the water supply, in the districts of London in 1849. The districts are arranged in the order of their mortality from cholera

District	Population	Deaths from cholera	Deaths from cholera per 10,000 inhabitants	Annual value of house and shop room to each person (in #)	Water supply
Rotherhithe	17,208	352	205	4.238	Southwark and Vauxhall Water Works, Kent Water Works, and Tidal Ditches
St. Olave, Southwark	19,278	349	181	4.559	Southwark and Vauxhall

settings. In the World Health Organization's Ten-Country Study, for instance, the incidence of nonaffective acute remitting psychosis was tenfold higher in developing than in developed country settings (Susser and Wanderling 1994). These studies have led to testing of specific hypotheses about causation, including antecedent fever and culturally normative life events.

Much useful public health information has been obtained from ecological studies. However, as will be illustrated throughout this chapter, both studies of individuals and studies with groups as the units of analysis have their limitations. The degree to which a given study design is appropriate depends on the particular research problem. Snow's research provides an illustrative example. Four years after Snow's initial investigation (illustrated in Table 5.2.2), one of the companies, the Lambeth Company, had moved its waterworks to a point higher up on the Thames, thus obtaining a supply of water free from the sewage of London. This meant that within a single district, some houses were receiving water drawn from one place on the Thames and others were receiving water drawn from a different point. Thus, the district as the unit of analysis was no longer appropriate. In Snow's words, 'To turn this grand experiment into account, all that was required was to learn the supply of water to each individual house where a fatal attack of cholera might occur' (cited in Susser 1973, p. 59). Snow subsequently confirmed the conclusions drawn from his prior ecological analysis by examining the relation between source of

Table 5.2.3 Cholera death rates by company supplying household water

Company	Number of houses	Deaths from cholera	Deaths per 10,000 houses
Southwark and Vauxhall Company	40,046	1263	315
Lambeth Company	26,107	98	37
Rest of London	256,423	1422	59

water and cholera risk with households, rather than districts, as the units of analysis (Table 5.2.3).

The next section, which focuses on 'fallacies' related to the existence of multiple levels of organization, discusses some of the limitations and potentialities of ecological studies and studies of individuals. The section begins with a discussion of the ecological fallacy because it is the fallacy most commonly mentioned in epidemiology. Other related fallacies that may occur even in studies with individuals as the units of analysis are also discussed.

The ecological fallacy and other fallacies related to the presence of multiple levels of organization

The ecological fallacy is the fallacy of drawing inferences at the individual level (i.e. regarding variability across individuals) based on group-level data. The most common example of the ecological fallacy involves situations in which group-level variables are used as proxies for unavailable individual level exposures. For example, in order to study the relation between exposure to substance X and cancer in the absence of individual level data, the prevalence of exposure to X in different areas is related to cancer rates in those areas. In this case, we do not have information on exactly who is exposed to X and who is not so the area prevalence of X is used as a rough approximation for the exposure of each area resident. Since we lack information on the joint distribution of exposure and outcome at the individual level (i.e. we do not know if persons who developed cancer were actually exposed to X) we cannot conclude that individuals exposed to X have a higher risk of lung cancer even if we find that areas with a higher percentage of people exposed to X have higher cancer rates. Another example is provided by attempts to draw inferences about the relation between income and obesity using countries as units of analysis and mean country income as a proxy for individual-level income data. Suppose a researcher finds that higher mean neighbourhood income is associated with higher mean body mass index (BMI). If he/she infers that at the individual level, higher income is associated with higher BMI, he/she may be committing the ecological fallacy, because there is no way of knowing whether within countries, individuals with higher income have higher BMI (in fact the opposite may be true, as we will discuss later in the chapter).

Sources of the ecological fallacy

The ecological fallacy arises when associations between two variables at the group level (or ecological level) differ from associations between analogous variables measured at the individual level. The typical ecological fallacy applies when aggregate measures for the group (e.g. the percentage of persons with a

certain attribute or the mean attribute across persons) are used as proxies for individual-level data. These differences between individual-level and group-level associations for apparently analogous variables were first described for correlation coefficients (Robinson 1950) but may also be present for other measures of associations such as linear regression coefficients (Morgenstern 1982). Because the use of correlation coefficients raises additional complexities (and because of its limitations as a measure of association), the following discussion will focus on regression coefficients as the main measure of association estimated at both the group and the individual level.

The example on income and BMI used earlier is schematically illustrated in Fig. 5.2.1. At the group or country level, mean BMI increases with increasing mean income. At the same time, for individuals within countries, BMI decreases with increasing individual-level income. This situation arises because group-level mean income is related to BMI independently of individual-level income (or in other words because there is a group effect). Persons living in countries with higher mean income generally have higher BMIs than those living in countries with lower mean income, regardless of their individual level income.

Another situation is depicted in Fig. 5.2.2, where the relation between individual-level income and BMI differs by mean country income: in countries with higher mean income, individual-level income is strongly and inversely related to BMI, whereas this relation is nonexistent, or perhaps exists in the opposite direction, in countries with lower mean income. Here the group-level variable (average income of the country in which a person lives) modifies the effect of individual-level income on the outcome. In this case, group-level associations (the relation between mean country income and mean country BMI) will also differ from individual-level associations (the relationship between individual-level income and individual-level BMI). In addition, individual-level associations will differ from country to country, according to levels of mean country income. Thus, when a group-level variable is related to the outcome independently of the analogous variable measured at the individual level, or when the group-level variable modifies the effects of its individual-level analogue on the outcome, ecological associations (which express the

Figures are schematic and are not intended to accurately represent relative magnitudes of coefficients.

Fig. 5.2.1 Hypothetical associations of income with body mass index (BMI) within and between countries. Mean country income does not modify the effect of individual-level income.

Fig. 5.2.2 Hypothetical associations of income with body mass index (BMI) within and between countries. Mean country income modifies the effect of individual-level income.

relationship between group-level variables and group-level outcomes) will differ from the corresponding individual-level associations (which express the relationship between individual-level variables and individual-level outcomes) (Hammond 1973; Firebaugh 1978; Greenland and Morgenstern 1989; Levin 1995).

The concepts just summarized can also be expressed mathematically. Suppose the ‘true’ relationship between country mean income, individual-level income, and individual-level BMI is reflected in Equation 5.2.1:

$$Y_{ij} = \beta_0 + \beta_1 X_{ij} + \beta_2 \bar{X}_j + U_j + e_{ij} \quad (5.2.1)$$

where:

Y_{ij} = BMI for i th individual in j th country.

X_{ij} = income for i th individual in j th country.

\bar{X}_j = mean X_{ij} in country j .

e_{ij} and U_j are individual-level and country-level errors, respectively.

β_1 = mean difference in individual-level BMI per unit difference in individual-level income.

β_2 = mean difference in individual-level BMI per unit difference in mean country income.

Thus, BMI for each individual is related not only to his or her own income, but also to the mean income for the country in which he or she lives. In Equation 5.2.1, β_1 reflects the individual-level relation between X_{ij} and Y_{ij} . Since it is ‘adjusted’ for the group effect (to the extent that between-group differences are entirely captured by β_2 and the group-level error U_j) it is equivalent to the within-group effect of individual-level income (or the average within-group effect if this varies across groups). β_1 is what we would like to estimate in order to quantify the individual-level effect of X_{ij} on Y_{ij} . β_2 reflects the relation between mean country income (\bar{X}_j) and Y_{ij} , after controlling for X_{ij} (i.e. the effect of mean country income on individual-level BMI after controlling for individual-level income). (Equation 5.2.1 can also be modified to allow interactions between X_{ij} and \bar{X}_j as shown in Fig. 5.2.2. For

reasons of simplicity this situation will not be illustrated, but the discussion that follows applies as well.)

Suppose that instead of this full equation showing the relationship between BMI and individual-level income and mean country income, we fit the ecological equation shown as follows:

$$\bar{Y}_j = \beta_{e0} + \beta_{e1} \bar{X}_j + e_j \quad (5.2.2)$$

where:

\bar{Y}_j = mean BMI in country j .

\bar{X}_j = mean income in country j .

β_{e1} = mean difference in mean country BMI per unit difference in mean country income. (The subscript e is used in this case because regression coefficients refer to ecological or group-level associations.)

In this case β_1 reflects the ecological relation between mean country income (\bar{X}_j) and mean country BMI (\bar{Y}_j). It is sometimes referred to as the between-group effect. Clearly, β_{e1} (the between-group effect) is not equivalent to β_1 (the within-group effect of X_{ij}) or β_2 (the effect of \bar{X}_j) in Equation 5.2.1. In fact both the individual-level within-group effect (β_1) and the effect of mean X_j (β_2) are confounded in the ecological regression coefficient (β_{e1}). In fact, β_e in Equation 5.22 is the sum of β_1 and β_2 in Equation 5.2.1 (Raudenbush and Bryk 2002)

Yet a third alternative is to fit a purely individual-level equation ignoring group membership:

$$Y_{ij} = \beta_{p0} + \beta_{p1} X_{ij} + e_{ij} \quad (5.2.3)$$

The subscript p is used in this case because regression coefficients refer to associations between individual-level variables pooled across groups. β_{p1} reflects the effect of X_{ij} on Y_{ij} pooling across groups and ignoring group membership (it is unadjusted for any potential group effects). When group effects are present, β_{p1} will differ from β_1 (the within-group effect) in Equation 5.21, and will also differ from β_{e1} (the ecological effect of \bar{X}_j) in Equation 5.2.2.

Both the within-group effects of X_{ij} and the effect of \bar{X}_j on Y_{ij} are confounded in β_{p1} .

In the absence of group effects (e.g. when β_2 in Equation 5.2.1 equals 0) and when there is no interaction between \bar{X}_j and X_{ij} (the group and individual-level variables), β_1 (within-group effect), β_{e1} (ecological effect), and β_{p1} (pooled individual effect) are all equivalent. However, in the presence of group effects, β_e does not equal β_1 or β_{p1} (source of the ecological fallacy). In addition, β_{p1} does not equal β_{e1} or β_2 . When group effects are present, β_{p1} will be a weighted average of β_1 and β_{e1} , and will lie between them, although the order of magnitude of β_1 and β_{e1} cannot be predicted (Piantadosi et al. 1988). β_1 (the within-group effect), β_2 (the contextual effect), β_{e1} , and β_{p1} are schematically illustrated in Fig. 5.2.1. The typical explanation given for the ecological fallacy in many epidemiology textbooks (i.e. the absence of cross-classified information on exposure and outcome within groups) is precisely the reason why β_2 and β_1 are confounded in β_e , and hence the reason why β_e cannot reliably be used to make inferences about β_1 when β_2 is nonzero.

It is important to note that although results for correlation coefficients generally follow those for regression coefficients outlined above, individual-level (within-group) and ecological (between-group) correlation coefficients may differ even in the absence of group effects (i.e. even when $\beta_1 = \beta_{e1} = \beta_{p1}$) (Hammond 1973; Piantadosi et al. 1988). This is because correlations also depend on the relative dispersion of X and Y (Morgenstern 1982; Piantadosi et al. 1988).

As illustrated above, ecological associations will differ from individual-level associations in the presence of group effects, i.e. when β_2 in Equation 5.2.1 does not equal 0 (or when the interaction between X_{ij} and \bar{X}_j in Equation 5.2.1 does not equal 0). The key to understanding the sources of the ecological fallacy therefore lies in specifying the conditions under which β_2 (the independent effect of \bar{X}_j) or the interaction between \bar{X}_j and X_{ij} will differ from 0. Several different situations may result in nonzero values for β_2 or for the interaction term between X_{ij} and \bar{X}_j . These include: (1) situations where group mean X_{ij} (\bar{X}_j) is a marker for omitted individual-level variables which individuals in a group tend to share, and (2) situations where mean X_{ij} at the group level measures a different construct than X at the individual level. Both situations will be discussed in more detail in the following subsections.

\bar{X}_j is a marker for omitted individual-level variables that individuals in a group tend to share

It is possible that \bar{X}_j is a marker for omitted individual-level variables that individuals in a group tend to share, that is, groups differ in the distribution of individual-level variables causally related to the outcome. In the earlier BMI example, unmeasured individual-level factors (e.g., diet, exercise, genetic factors) may vary from country to country, and their prevalence may be associated with mean country income. These individual-level factors may affect the risk of the outcome independently of individual-level income or may modify the association of individual-level income with the outcome. If these factors are unmeasured in the analyses, their effects will be reflected in the coefficient for mean income in Equation 5.2.1 (β_2) (or in the mean income by individual-level income interaction), and in the ecological regression coefficient relating mean income to mean BMI (β_{e1} in Equation 5.2.2). Thus, differences in

the distribution of these individual-level confounders or effect modifiers across groups may lead to discordances between the group-level and individual-level associations of income with BMI. Summary ecological measures of these individual-level factors for each group are sometimes available (e.g. percentage sedentary, or mean dietary fat). However, controlling for these summary measures in ecological analyses is often insufficient to account for the confounding effects of individual-level variables (although in some cases controlling for multiple summary measures of the same variable may reduce confounding to some extent) (Greenland and Morgenstern 1989; Greenland and Robins 1994; Morgenstern 1995). It is even possible for this ecological adjustment to actually increase bias (Greenland and Morgenstern 1989). The limitations of the use of summary measures are especially important when the relationship between individual-level factors and the outcome is nonlinear, when individual level factors interact or when there is measurement error (Greenland 1992; Greenland and Robins 1994; Piantadosi 1994).

An additional complexity arises from the fact that even an individual-level variable that is not a confounder at the individual level (because it is not associated with exposure within groups) may still operate as a confounder when ecological associations are used to draw individual-level inferences, if it is ecologically associated with the exposure prevalence across groups (Greenland and Morgenstern 1989; Greenland 1992). Similarly, even weak effect modifiers at the individual level may lead to important differences between ecological and individual-level associations, if their prevalence differs across groups (Greenland and Morgenstern 1989). On the other hand, a variable that is a confounder at the individual level (because it is associated with the exposure and the outcome within groups) may not confound the analogous ecological association if it is ecologically unassociated with the exposure across groups (Greenland and Robins 1994; Morgenstern 1995) (i.e. the grouping process itself may control for some confounding variables) (Morgenstern 1982). Brenner et al. (1992) have also shown that although nondifferential misclassification of a binary variable seriously hinders the ability to control for that variable in individual-level studies, it does not always reduce the ability to control for that variable in ecological studies. Thus in some cases, the ecological analysis may avoid the confounding present in individual-level analyses.

The absence of information on individual-level confounders (which may differ from group to group) and the limitations inherent in using ecological summaries (and interactions between ecological summaries) to control for individual-level confounders or account for nonlinearities in the individual-level effects, is the most common critique of ecological studies in epidemiology. A key assumption of this critique (which often goes unstated) is that the ecological measures (e.g. mean country income) and the individual-level measures (individual-level income) are indicators of the same construct. If it were somehow possible to control for the individual-level confounders and fully capture nonlinearities, it would be perfectly legitimate to draw inferences about associations between individual-level income and BMI based on the ecological association. But this assumption is not always true. Even if all possible individual-level confounders are controlled, ecological associations may differ from individual-level associations because the ecological measure of exposure and its individual-level name-sake may be tapping into different constructs. This brings us to

another important source of the ecological fallacy, discussed in the next subsection.

\bar{X}_j and X_{ij} measure different constructs

An alternative interpretation of Fig. 5.2.1 (or Fig. 5.2.2) is that country mean income and individual-level income are measuring different constructs (\bar{X}_j measures a group-level construct and X_{ij} measures a different individual-level construct), and the group-level construct is related to BMI independently of individual-level income. Firebaugh (1978, p. 560) noted that ‘The demystification of cross-level bias begins with the recognition that an aggregate variable often measures a different construct than its name-sake at the individual-level’. In this case, country mean income is a measure of a truly group-level attribute and not a proxy for individual-level income. Living in countries with high mean income places individuals at greater risk of having a high BMI regardless of their individual-level income (or modifies the relation between individual-level income and BMI, as in Fig. 5.2.2). Mean country income is said to exert a contextual effect on BMI. Both country-level and individual-level income provide distinct information, and both are needed to completely explain the distribution of BMI. In this case, the origin of the ecological fallacy lies in assuming that the group level measure is tapping into the same construct as the individual-level measure, when in fact it is not. Higher mean country income is associated with higher BMI, after controlling for individual-level income, but within countries, higher individual-level income is associated with lower BMI. In this situation the ecological fallacy can be thought of as a problem of construct validity: it arises because the aggregate measure is assumed to be measuring an individual-level construct when in fact it is measuring a group-level construct (Schwartz 1994).

The contextual effect of mean income may be due to a variety of different processes. For example, countries with higher mean income may rely to a greater extent on mass food production, and this may in turn be associated with higher calorie intake for all individuals. In addition, the higher mean income may be associated with differences in country occupational structures resulting in more sedentary occupations. Since disease is defined at the level of individuals, in order to affect health, contextual effects must ultimately be mediated through individual-level processes (i.e. through processes defined at a lower level of organization), just as the effects of individual-level behaviours, for example, are mediated through biological mechanisms. Mediators of a contextual effect do not necessarily involve the individual-level namesake of the group-level variable. In our BMI income example, for instance, the contextual effect of mean income may work through individual level variables other than income. It is also possible that the apparent contextual effect of the group-level variable is confounded by another group-level variable. For example, in our example higher mean income may not in itself be the cause of higher BMI. It may simply be associated with level of industrialization which is the truly causally relevant construct.

Grouping on the dependent variable

Hammond (1973) notes another (related) reason for differences between ecological and individual-level regression coefficients: grouping by the dependent variable. For example, if people are grouped into neighbourhoods based on their income (due to social processes driving economic residential segregation) and we are interested in estimating the relationship between race and

income at the individual level, the ecological regression coefficient relating percentage of black and mean neighbourhood income would differ from the individual-level coefficient relating race to individual-level income because of the grouping process involved. Similarly, if people were grouped into neighbourhoods based on the presence of disease, and we are interested in the relationship between a certain risk factor and disease, the ecological relation between the percentage of people in the neighbourhood with the risk factor and the disease rate would be a biased estimate of the individual-level association between the risk factor and the probability of having the disease. Essentially, the grouping process generates a ‘group effect’ analogous to the contextual effects of mean group X described earlier.

Relationship between sources of the ecological fallacy

The three sources of the ecological fallacy described earlier all pertain to situations where there is some form of ‘group-effect’. This includes situations where there is a failure to distinguish constructs at different levels (e.g. mean group X is assumed to measure the same thing as individual-level X), where something about the groups is associated with individual-level predictors of the outcome (mean group X is associated with other individual-level factors related to Y), or when some process results in grouping of persons by the dependent variable. It is important to emphasize that the simple presence of differences in the distribution of individual-level variables (e.g. diet and exercise in our example) across groups (countries in our example) may be an indication that group-level constructs play a causal role in the development of these individual-level factors. In common epidemiological discussions of the ecological fallacy, these group effects are viewed as a nuisance that makes it difficult for epidemiologists to draw inferences regarding individual-level associations based on group-level data. However, more recently, epidemiologists have become increasingly interested in investigating these group effects.

The previous discussion (like typical discussions of the ecological fallacy) focuses on the situation where the independent variable at the group level is an aggregate of characteristics of individuals in the group. Thus the group-level variable (mean income) has an individual-level namesake (individual-level income). However, other ecological variables do not involve aggregates of individual-level data (e.g. the existence of a certain law) and the problem of separating out contextual effects from individual-level effects of the variable (e.g. the effects of mean country income from that of individual-level income) is not an issue. In this situation it is obvious that the ecological variable is measuring a group-level construct. However, ecological studies relating these types of predictors to outcomes may still be limited in their ability to draw individual-level inferences because of the absence of information on individual-level confounders or effect modifiers which may differ from group to group.

Other reasons for differences between ecological and individual-level regression coefficients

In addition to the conceptual issues discussed previously, there are statistical considerations that may lead to a discrepancy between estimates from ecological and individual-level studies. The example used throughout this section (country mean income, individual-level income, and BMI) is based on a continuous individual-level dependent variable and highlights the limitations inherent in using a linear ecological model as a proxy for a

linear individual-level model. Additional complexities arise when the individual-level outcome is binary. The use of a linear regression ecological model as a proxy for a nonlinear individual-level regression model (e.g. a log-linear or multiplicative model) may not always be appropriate. Fitting the aggregate or ecological regression model that directly corresponds to a nonlinear individual-level regression model is not always simple or possible with available ecological data (see Greenland 1992 for details). Failure to correctly specify the ecological model to be used as a proxy for the individual-level model (sometimes referred to as specification bias; Wakefield 2008) is another source of differences between individual-level and aggregate-level regression coefficients. However, all the sources of the ecological fallacy described in the preceding sections may still be present even if the form of the ecological model is appropriate for the individual-level model it is attempting to proxy.

It is important to emphasize that the degree to which ecological and individual-level coefficients differ may vary from situation to situation. The logical possibility of the ecological fallacy should not be taken as evidence that the fallacy necessarily occurs in all cases (Greenland and Robins 1994) or that when it occurs it has a critical impact. Some researchers have proposed strategies that may sometimes help reduce the ecological fallacy, particularly when the group-level aggregate exposure is simply a proxy for unavailable individual-level data. These strategies include selecting regions so as to minimize within-region variability and maximize between-region variability in individual-level exposure, comparing groups with similar covariate distributions, comparing results based on different specifications of the ecological model (Greenland 1992), two-phase designs that combine ecological data with samples of individual within groups (Wakefield and Haneuse 2008), and other statistical approaches (King 1997; Wakefield 2008). Many of these approaches assume that no other group-level effects are present or that the aggregate proxy is not serving as a proxy for group-level constructs. Despite these approaches, and for all the reasons outlined, the use of ecological studies to estimate individual-level relationships is often very challenging (Greenland 2001; Wakefield 2008).

Other fallacies related to the existence of multiple levels

The ecological fallacy is only one of a set of possible ‘fallacies’ that can result from the existence of multiple levels of organization (Diez-Roux 1998). Because, until relatively recently, epidemiologists have been mostly concerned with drawing inferences regarding the causes of interindividual variability, the ecological fallacy has received much more attention than its counterpart, the atomistic fallacy. The atomistic fallacy is the fallacy of drawing inferences regarding variability across groups based on individual-level data. The association of an individual-level predictor with an outcome in a study of individuals is not necessarily the same as the association of its group level namesake with the group-level outcome. Thus the use of individual-level associations to draw inferences regarding group-level associations may also lead to incorrect inferences. In the BMI example, β_{p1} (the relation between individual-level income and BMI pooling individuals across groups) does not equal β_{e1} (the ecological relation between country mean income and country mean BMI). In addition, β_1 (the within-group effect of individual-level income) does

not equal β_{e1} either. Moreover, the BMI example includes multiple groups (countries) and individuals within them, but many individual-level studies only include individuals from a single group. Factors that explain variability across individuals within groups are not necessarily the same as those that explain variability across groups. For example, if stress levels are relatively invariant within groups (e.g. communities or countries), stress may not be important in explaining variability in coronary heart disease within groups, but may be strongly associated with differences in coronary heart disease rates across groups. This is another reason why the use of individual-level associations to infer group-level associations may lead to incorrect inferences.

The ecological and atomistic fallacies can be thought of as methodological problems inherent in drawing inferences at one level when the data are collected at another level. These fallacies arise when the conceptual model being tested corresponds to one level, but the data are collected at another level, or in Riley’s words when ‘the methods fail to fit the model’ (Riley 1963). We have seen that the sources of these problems lie in: (1) the lack of information on constructs pertaining to another level of organization, and (2) the failure to realize that a variable defined and measured at one level of organization may tap into a different construct than its namesake at another level, and that constructs at both levels may be relevant to the outcome studied.

More generally, careful consideration of the sources of the ecological and atomistic fallacies highlights the fact that even when making inferences about a given level, other levels of organization may need to be taken into account. The failure to consider group characteristics in drawing inferences regarding the causes of variability across individuals, and the failure to consider individuals in drawing inferences regarding the causes of variability across groups, gives rise to another set of fallacies, which are closely related to the ecological and atomistic fallacies described earlier. In these fallacies (which have been termed the psychologistic or individualistic and sociologistic fallacies), although the level at which data are collected may fit the conceptual model being investigated, important facts pertaining to other levels have been ignored, in Riley’s words ‘the methods may fail to fit the facts’ (Riley 1963).

Ignoring relevant group-level variables in a study of individual-level associations may lead to what Riley has termed the psychologistic fallacy, that is, assuming that individual-level outcomes can be explained exclusively in terms of individual-level characteristics. For example, a study based on individuals might find that immigrants are more likely to develop depression than natives. But suppose this is only true for immigrants living in communities where they are a small minority. A researcher ignoring the contextual effect of community composition might attribute the higher overall rate in immigrants to the psychological effects of immigration per se or even to genetic factors, ignoring the importance of community-level factors and thus committing the psychologistic fallacy (Riley 1963; Valkonen 1969). (The term ‘psychologistic fallacy’ is not the most appropriate because the individual-level factors used to explain the outcome are not always exclusively psychological. Other authors have used the term ‘individualistic fallacy’ (Valkonen 1969), but because the term has also been used as a synonym of the ‘atomistic fallacy’ (Alker 1969; Scheuch 1969) it will be avoided here.)

Analogously, ignoring the role of individual-level factors in a study of groups may lead to what has been termed the sociologistic fallacy (Riley 1963). Suppose a researcher finds that communities with higher rates of transient population have higher rates of schizophrenia, and he/she concludes that higher rates of transient population lead to social disorganization, breakdown of social networks, and increased risk of schizophrenia among all community inhabitants. But suppose that schizophrenia rates are only elevated for transient residents (because transient residents tend to have fewer social ties, and individuals with few social ties are at greater risk of developing schizophrenia). That is, rates of schizophrenia are high for transient residents and low for nontransient residents, regardless of whether they live in communities with a high or a low proportion of transient residents. If this is the case, the researcher would be committing the sociologistic fallacy in attributing the higher schizophrenia rates to social disorganization affecting all community members rather than to differences across communities in the percentage of transient residents.

Both the psychologistic and the sociologistic fallacies arise because relevant variables pertaining to other levels have been excluded from the model leading to an inappropriate explanation for the association. Although it is didactically useful to distinguish both sets of fallacies (ecological and atomistic vs. psychologistic and sociologistic), they are closely interrelated and are essentially different manifestations of the same phenomenon: the failure to recognize that constructs defined at different levels may be important in understanding the causes of variability within a given level, and the failure to adequately distinguish constructs defined at different levels.

The types of fallacies are summarized in Table 5.2.4.

The full range of epidemiological studies

In considering the most appropriate study design to answer a given research question, investigators need to consider two issues. The first issue is the level of organization about which inferences are to be made. For example, are we interested in drawing inferences regarding causes of variation in the outcome among groups or among individuals? The answer to this question will determine the most appropriate unit of analysis. The second issue is the level

of organization at which the constructs of interest in explaining the outcome are conceptualized. The answer to this second question will determine the predictors to be investigated and the level at which they are conceptualized. Constructs relevant to health may be conceptualized, and measured, at different levels of organization (e.g. countries, states, neighbourhoods, peer groups, families, couples, persons, and measurement occasions). Factors defined at a higher level may be important in understanding variability at a lower level and, vice versa, factors defined at a lower level may be important in understanding variability at a higher level. Decoupling the unit of analysis from the level of organization of the constructs investigated may be helpful in discussing the full range of studies available to epidemiologists and the advantages and disadvantages of each for a particular research question.

Clearly specifying the constructs of interest is an important requirement of any study. Lack of clarity on exactly what constructs group-level or ecological variables are actually measuring underlies an important part of the confusion generated by the use of ecological studies and the interpretation of group-level or ecological associations. The next subsection reviews the use of group-level variables in epidemiology based on the constructs that they are intended to measure. The subsequent subsection considers study designs with different units of analysis in terms of the types of inferences that can be drawn from them and the types of constructs they are best suited to investigating.

Group-level variables in epidemiology

Group-level variables as proxies for individual-level variables

One of the most common uses of ecological variables in epidemiological studies is as proxies for individual-level variables, either because individual-level data are unavailable or because individual-level measurements are prone to measurement error. For example, in the absence of detailed information on smoking for individuals, the percentage of smokers in the area in which an individual lives may be used as a proxy. Of course, the use of these group-level proxies implies loss of information: we do not know whether a given person smokes or not; we use mean smoking levels in the area as an approximation. In this case the group-level measure is a second class alternative to the ideal individual-level measurement. The relevant construct (smoking) is defined at the individual level, but a group-level measurement is used as a proxy for it because direct individual-level measurements are unavailable. If a valid and reliable measure of individual-level exposure were available, it would be used instead.

Group-level variables are also used as proxies for individual-level data in cases in which individual-level measures are subject to a lot of measurement error, or when intraindividual variability makes a single measure a poor marker for the person's true exposure. For example, the mean yearly hours of sunlight in an area may be used as a proxy for individual-level exposure to sunlight and average per capita fat consumption in a group may be used as a proxy for the fat consumption of each member (due to limitations in characterizing an individual's fat intake based on a single, 1-day measurement). In these situations, the ecological measure is believed to be a better indicator of the 'true' individual level exposure than the individual level measure itself, because the ecological measure reduces the 'noise' associated with measurement error or intra-individual variation.

Table 5.2.4 Types of fallacies

Unit of analysis	Level of inference	Type of fallacy
Group	Individuals	Ecological
Individual	Groups	Atomistic ^a
Individual (relevant group-level variables excluded)	Individuals	Psychologistic ^a
Group (relevant individual-level variables excluded)	Groups	Sociologistic

^a Also called individualistic by some authors.

Group-level proxies for individual-level variables can be used in studies with individuals or groups as the units of analysis. Regardless of the study design in which they are used, the key assumption in the use of these variables is that the group-level measure is an adequate proxy for the individual-level construct, that is, even if there is measurement error, the construct that is being tapped into by the measure is an individual-level property rather than a group-level property. But this may not always be true: it is possible that the group-level measure is capturing information about a group-level attribute rather than about individual-level characteristics. For example, mean neighbourhood income could be used as a proxy for unavailable information on the income of residents. It is theoretically possible that areas with lower income have worse health not because people of low income have worse health but because there is something about areas with a lower income that places everyone in the area at higher risk regardless of their own income. Unless individual-level data are available, it will not be possible to differentiate the effects of individual-level income from the contextual effect of mean income (or other group-level properties associated with it). Thus, in considering the use of group-level variables as proxies of individual-level data, researchers should consider two issues: (1) the degree of measurement error in the individual-level construct inherent in using the group-level variable (e.g. misclassification of smokers as nonsmokers), and (2) the degree to which the group-level measure is tapping into a group-level construct rather than the individual-level construct it purports to proxy.

Group-level (higher-level) variables as measures of group-level (higher-level) constructs

Another application of ecological variables is to measure group-level constructs. Variables that reflect the characteristics of groups have been classified into two basic types (Valkonen 1969; Lazarsfeld and Menzel 1971; Blalock 1984; Von Korff et al. 1992; Morgenstern 1995): derived variables and integral variables. Derived variables (also termed analytical or aggregate variables) summarize the characteristics of individuals in the group (means, proportions, e.g. percentage of persons with incomplete high school, median household income). Although created through the aggregation of information from the individual members of a group, derived variables are often used as measures of group-level properties since they can provide information distinct from their individual-level analogue. For example, mean neighbourhood income, and individual-level income are indicators of two distinct constructs, each of which may be important to health. Mean neighbourhood income may be a marker for neighbourhood-level factors potentially related to health (such as recreational facilities, school quality, road conditions, environmental conditions, types of foods available, and their cost), and these factors may affect everyone in the community regardless of their individual-level income. Similarly, community unemployment level is a community-level property that may affect everyone in the community regardless of whether they are unemployed or not.

A special subset within derived variables is the average of the dependent variable within the group (Susser 1994a, 1994b). As noted by Ross in his theory of happenings (Ross 1916), for some types of events, the frequency of occurrence may depend on the number of individuals already affected. The prevalence of a given infection in the group to which a person belongs will affect

his or her risk of infection, or may modify the relation between individual-level risk factors and the risk of disease (Halloran and Struchiner 1991; Koopman et al. 1991; Koopman and Longini 1994). The classic concept of herd immunity is a variant of this notion: the prevalence of immunity in a community will influence whether an epidemic of disease does or does not occur, and will therefore affect a nonimmune individual's risk of acquiring disease. The contextual effect of the dependent variable's prevalence within a group may also be important in understanding other health outcomes. For example, the prevalence of obesity in a community may influence the likelihood that an individual is obese. This effect may operate through several different mechanisms. The prevalence of obesity may itself generate societal norms regarding acceptability and desirability of obesity, which may influence an individual's risk of being obese. In addition, the probability of adopting behaviours conducive to obesity (e.g. certain types of diet or physical activity patterns) may be higher in situations where the behaviour is highly prevalent in the community. Although infrequently considered, these types of contextual effects may be important in understanding the distribution (and causes) of health-related behaviours.

Integral variables (also termed primary or global variables) describe group characteristics that are not derived from characteristics of its members (e.g. the existence of certain types of laws, availability of health care, political system, or population density). Integral variables do not have analogues at the individual level. They may be discrete and dichotomous (e.g. an intervention or a disaster, presence of a certain law), scaled and polychotomous (e.g. social disorganization, intensity of newborn care), or continuous (e.g. physicians per capita). A special type of integral variable refers to patterns and networks of contacts or interactions between individuals within groups. These patterns are derived from how individuals are connected to each other, and yet they are more than aggregates of individual characteristics. Lazarsfeld and Menzel (1971) have referred to these variables as structural variables although the term structural effects has also been used to refer to the effects of group-level properties more generally (Blau 1960). Patterns of interconnections among individuals may be important determinants of individual risk, particularly for infectious diseases, but possibly for many other health outcomes as well (Koopman et al. 1991; Koopman and Longini 1994; Koopman and Lynch 1999). In addition, these patterns of interconnections may modify the relation between certain individual-level attributes and risk of disease (Koopman et al. 1991). Patterns of interactions can be summarized in the form of group-level attributes such as network size or structure (Lazarsfeld and Menzel 1971; van den Eeden and Huttner 1982). Just as other 'group-level' variables can refer to groups of various sizes, these patterns of interactions may characterize a whole continuum of groups depending on the particular research problem: large groups, smaller groups within larger groups, or even pairs of individuals.

When group-level variables are used to characterize group-level properties there is no ambiguity in defining whether individuals are or are not exposed (as there is when group variables are used as proxies for individual level exposure data). The group level variable (whether derived or integral) applies equally to all individuals within the group: for example, all are 'exposed' to living in a neighbourhood with high unemployment regardless of whether they themselves are employed, all are 'exposed' to existing laws

regarding seat belt use. Thus the measurement error problem that may be present when group measures are used as proxies for measures of individual-level constructs is not present (although there may of course be measurement error in the measure of the group-level construct itself, as there may be for any measure). When derived variables (such as area mean income or area unemployment) are used to capture group-level constructs, in the absence of individual-level data it will not be possible to distinguish a true group or contextual effect from an individual-level effect. But this problem does not arise with integral variables because no individual-level analogue exists. As we discuss later, group-level constructs can be investigated in studies with either individuals or groups as the units of analysis.

Study designs based on the units of analysis

Studies with groups as units of analysis

Studies with groups as the units of analysis (ecological studies) are most appropriate when investigators are interested in explaining variation between groups and the constructs of interest can be conceptualized as group-level properties. These group-level properties may be characterized using derived or integral variables. For example, numerous ecological studies have examined the relationship between area measures of deprivation (derived variables) and area disease or mortality rates (see, e.g. Townsend et al. 1988; Wing et al. 1992; Benach et al. 2001; Janghorbani et al. 2006). This analytical approach is most appropriate if the research question is formulated at the area (group)-level and the main construct investigated (deprivation) is conceptualized as an area or group-level attribute. In these cases, area deprivation is conceptualized as a group attribute that affects all individuals living within the community and the interest lies in drawing inferences regarding differences between areas.

An example involving integral group-level variables is provided by studies relating national legislation restricting tobacco advertising in different countries to country smoking rates: a country-level construct is examined and the interest lies in drawing country-level inferences. Ecological designs may also be appropriate for the evaluation of the effects of group-level interventions on group-level outcomes (Morgenstern 1982). For example, a study may want to investigate the relationship between the introduction of a mass media campaign to prevent teenage smoking (an integral variable) and the prevalence of teenage smoking in the area. Because the mass media campaign may affect all community inhabitants (regardless of whether they actually saw the ads or not) through mechanisms involving diffusion, peer pressure, etc., the intervention can be conceptualized as a group-level attribute.

As discussed earlier in the section on the ecological fallacy, these studies are limited in their examination of the role of individual-level constructs—as confounders, mediators, or effect modifiers of the group-level associations. In the earlier example, differences in the effects of the mass media campaign by individual-level characteristics (effect modification) could not be investigated. Neither could the impact of differences in individual exposures to the mass media campaign. In addition, in the case of ecological variables with individual-level analogues (e.g. area unemployment and individual-level unemployment), studies with groups as the units of analysis cannot differentiate the contextual effect of the variable from its individual-level effect. For example,

an ecological study showing that area unemployment is related to higher rates of adverse mental health outcomes could not differentiate whether the increased rate of mental illness is seen only in the unemployed or is present in all area inhabitants regardless of whether they are unemployed or not. However, from a public health perspective, the group-level association may itself be of great interest. If the association observed is causal, decreasing the unemployment rate would decrease the rate of mental illness regardless of whether the effect was due to the group or individual effect of unemployment. Similarly, the country-level relationship between income inequality and health may have important policy implications regardless of whether it is due to a contextual effect of income inequality itself, or to the fact that more unequal countries tend to have more people in the lower-income categories.

It is often argued that ecological studies may be particularly useful when investigating the health effects of individual-level attributes with little within-group variation but large between-group variation. For example, if dietary fat is homogeneous within countries but varies greatly from country to country, an individual-level study restricted to individuals from a single country may find no association between dietary fat and cardiovascular disease, but an ecological study comparing country rates to country average fat intake may find a strong relationship. From this perspective, the advantage of the ecological study results purely from the fact that it is able to include more variability in the exposure of interest. The same research question could be addressed in a study of individuals that included individuals from different countries and thus ensured sufficient variation in the exposure. But often this option is not feasible, whereas country-level measures may be available from standard sources. Of course, the presence of significant between-country differences in diet raises the important question of why countries differ in diet to begin with, and suggests that the diet of individuals has important country-level determinants. Despite the potential advantage of increasing variability in the exposure of interest, ecological studies of diet and health outcomes are subject to the limitations of ecological studies outlined earlier in terms of the inability to control for individual-level variables which may vary from group to group and the possibility of confounding by other group-level variables.

Although they will not be discussed here in detail, studies with groups as the units of analysis are subject to many of the same analytical issues as individual-level studies with respect to confounding, establishment of temporality, selection biases, etc. In addition, these types of analyses raise additional methodological issues, such as the need to have adequate numbers of groups as well as enough individuals per group, the need to account for differences in the variability of outcomes (i.e. estimated rates) for the different groups due to the fact that they may be based on different numbers of observations, and the possibility of multicollinearity between the predictors examined (which is often more of a problem in ecological studies than in individual-level studies) (Morgenstern 1982). In addition, studies in which the units of analysis are geographic areas may need to use statistical methods to account for the fact that areas geographically closer to each other may tend to be more similar (in outcomes) than those more distant from each other (due to unmeasured factors that cluster in space), which leads to violation of the assumption of independence of observations (e.g. Clayton et al. 1993; Zhu et al. 2006).

Time-trend studies also raise additional methodological issues related to time-series analyses generally (Morgenstern 1995).

Studies with individuals as units of analysis

Individual-level studies are most appropriate when investigators are interested in drawing inferences regarding variability across individuals, and all potential constructs of interest can be conceptualized as individual-level properties. The most common epidemiological studies are of this type. The assumption is that all constructs relevant to the outcome being studied are individual-level constructs.

Studies with individuals as the units of analysis and with information limited to individual-level constructs cannot examine the role of group-level constructs as antecedents of individual-level variables, as independent predictors of outcomes, or as confounders of individual-level associations. They cannot determine whether the effect of a given individual-level variable is only present in certain group contexts, or varies from group to group, as a function of group characteristics. In order to answer these questions, other types of studies are needed.

Studies limited to individuals from a single group are clearly unable to examine the role of group-level constructs in causing the outcome (or in interacting with individual-level variables), because group-level properties are invariant within groups (Schwartz and Carpenter 1999). If group-level factors are important in causing the outcome, studies focused on a single group may fail to detect important disease determinants. In the dietary fat example mentioned earlier, we noted that a study based on individuals from a single country would not detect dietary fat as a risk factor if it were invariant within countries. More fundamentally, the country-level factors that influence large variations in fat intake across countries is the salient variable that the individual-level study could not capture.

If the study involves individuals from many different groups, relevant group-level properties may be included in individual-level analyses. For example, group-level variables can be included in regression equations with individuals as the units of analysis. These types of analyses have been called contextual analyses (Blalock 1984; Iversen 1991). Susser (1994) has referred to studies that investigate the effects of group-level variables on individual-level outcomes as mixed studies. A simple example of the type of regression models fitted in contextual analysis is shown in Equation 5.2.4:

$$Y_{ij} = \beta_0 + \beta_1 C_j + \beta_2 X_{ij} + e_{ij} \quad (5.2.4)$$

where:

Y_{ij} = outcome for i th individual in j th group.

C_j = group-level variable.

X_{ij} = individual-level variable.

e_{ij} = error for i th individual in j th group.

Contextual models can include multiple group-level and individual-level variables as well as their interactions. In the model shown in Equation 5.2.4, β_1 estimates the effect of the group-level characteristic on the individual-level outcome (after adjustment for X_{ij}) and β_2 estimates the effect of the individual-level variable on the outcome (after adjustment for C_j). Contextual models

can be used, for example, to investigate the effects of neighbourhood context on fertility outcomes by including characteristics of the neighbourhoods where individuals live (derived or integral variables) together with individual-level characteristics in individual-level regression models.

In these models, special methods may be necessary to account for residual within-group correlations in individual-level outcomes. Ignoring this correlation may lead to incorrect estimates of standard errors (Diggle et al. 2002). Efficiency of estimation may also be reduced (Diggle et al. 2002). One common approach to account for within-group correlations is to use marginal models (Zeger et al. 1988), also referred to as population-average models (Diggle et al. 2002) or covariance pattern models (Brown and Prescott 1999). Marginal or population-average models model the population-average response as a function of covariates without explicitly accounting for heterogeneity across groups (Zeger et al. 1988). In contrast to the multilevel models described in the next subsection, marginal models do not allow examination of group-to-group variability per se, or of the factors associated with it. Neither do they allow decomposition of total variability in the individual-level outcome into within- and between-group components. Although contextual analysis can be used to simultaneously investigate the effects of group-level and individual-level constructs in shaping individual-level outcomes it does not allow examination of group-to-group variability per se, or of the factors associated with it. The unit of analysis remains the individual and only interindividual variation is examined.

Studies with both groups and individuals as the units of analysis (multilevel studies)

Multilevel studies and multilevel analysis have gained increasing recognition and use in several fields including education, sociology, and public health (Mason et al. 1983; Hermalin 1986; Paterson and Goldstein 1991; DiPrete and Forristal 1994; Duncan et al. 1998; Kreft and deLeeuw 1998; Diez Roux 2000, 2002; Raudenbush and Bryk 2002; Subramanian 2003; Bingenheimer and Raudenbush 2004). Multilevel studies simultaneously examine groups (or samples of groups) and individuals within them (or samples of individuals within them). Variability at both the group level and the individual level can be simultaneously examined and the role of group-level and individual-level constructs in explaining variation between individuals and between groups can be investigated. For example, a study may have information on a series of country-level characteristics (e.g. gross national product, inequality in the distribution of income) and on the individual-level characteristics of a sample of individuals within each country (including health outcomes). Researchers may be interested in investigating how country-level and individual-level factors are related to health outcomes, as well as the extent to which between-country and between-individual variability in the outcomes are explained by variables defined at both levels. Thus, multilevel analysis allows researchers to deal with the micro-level of individuals and the macro-level of groups or contexts simultaneously (Duncan et al. 1998). Multilevel models can be used to draw inferences regarding the causes of interindividual variation and the extent to which it is explained by individual-level or group-level variables, but inferences can also be made regarding intergroup variation, whether it exists in the data, and to

what extent it is accounted for by group and individual-level characteristics.

In the case of multilevel analysis involving two levels (e.g. individuals nested within groups), the model can be conceptualized as a two-stage system of equations. The case for a normally distributed dependent variable is illustrated in Equation 5.2.5. For reasons of simplicity, the illustration will focus on the case of only one independent variable at the individual and one independent variable at the group level (although models can of course be extended to include as many independent variables as needed).

In the first stage, a separate individual-level regression is defined for each group.

$$Y_{ij} = \beta_{0j} + \beta_{1j}I_{ij} + e_{ij} \quad e_{ij} \sim N(0, \sigma^2) \quad (5.2.5)$$

where:

Y_{ij} = outcome variable for i th individual in j th group (or context).

I_{ij} = individual-level variable for i th individual in j th group (or context).

β_{0j} is the group-specific intercept.

β_{1j} is the group-specific effect of the individual-level variable.

Individual-level errors (e_{ij}) within each group are assumed to be independent and identically distributed with a mean of 0 and a variance of σ^2 . Regression coefficients (β_{0j} and β_{1j}) are allowed to vary from one group to another.

In a second stage, each of the group or context-specific regression coefficients defined in Equation 5.2.1 (β_{0j} and β_{1j} in this example) are modelled as a function of group-level variables:

$$\beta_{0j} = \gamma_{00} + \gamma_{01}C_j + U_{0j} \quad U_{0j} \sim N(0, \tau_{00}) \quad (5.2.6)$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}C_j + U_{1j} \quad U_{1j} \sim N(0, \tau_{11}) \quad (5.2.7)$$

$$\text{cov}(U_{0j}, U_{1j}) = \tau_{10}$$

where:

C_j = group-level or contextual variable.

γ_{00} is the common intercept across groups (where C_j is 0).

γ_{01} is the effect of the group-level predictor on the group-specific intercepts.

γ_{10} is the common slope associated with the individual-level variable across groups (where C_j is 0).

γ_{11} is the effect of the group-level predictor on the group-specific slopes.

The errors in the group-level equations (U_{0j} and U_{1j}), sometimes called 'macro errors', are assumed to be normally distributed with mean 0 and variances τ_{00} and τ_{11} respectively. τ_{01} represents the covariance between intercepts and slopes; for example, if τ_{01} is positive, as the intercept increases the slope increases. Thus, multilevel analysis summarizes the distribution of the group-specific coefficients in terms of two parts: a 'fixed' part which is unchanging

across groups (γ_{00} and γ_{01} for the intercept, and γ_{10} and γ_{11} for the slope) and a 'random' part (U_{0j} for the intercept and U_{1j} for the slope) which is allowed to vary from group to group.

By including an error term in the group-level equations (Equations 5.2.6 and 5.2.7), these models allow for sampling variability in the group-specific coefficients (β_{0j} and β_{1j}) and also for the fact that the group-level equations are not deterministic (i.e. the possibility that not all relevant macro-level variables have been included in the model) (Wong and Mason 1985). The underlying assumption is that group-specific intercepts and slopes are random samples from a normally distributed population of group-specific intercepts and slopes (or equivalently, that the groups or macro errors are 'exchangeable') (DiPrete and Forristal 1994).

An alternative way to present the model fitted in multilevel analysis is to substitute Equations 5.2.6 and 5.2.7 in Equation 5.2.5 to obtain:

$$Y_{ij} = \gamma_{00} + \gamma_{01}C_j + \gamma_{10}I_{ij} + \gamma_{11}C_jI_{ij} + U_{0j} + U_{1j}I_{ij} + e_{ij} \quad (5.2.8)$$

The model includes the effects of group level variables (γ_{01}), individual-level variables (γ_{10}) and their interaction (γ_{11}) on the individual-level outcome Y_{ij} . It also includes a random intercept component (U_{0j}), and a random slope component (U_{1j}), which together with the individual-level errors e_{ij} compose a complex error structure. Because of the presence of this complex error structure, special estimation methods must be used. Although multilevel or random effects models were first developed for continuous dependent variables, analogous methods have been developed for other types of outcomes (Wong and Mason 1985; Raudenbush and Bryk 2002; Hox 2010; Snijders and Bosker 2011; Goldstein 2011).

By simultaneously including information on both groups and individuals, multilevel models avoid the limitations of ecological studies and individual-level studies outlined in the earlier section on fallacies. Both individuals and groups are units of analysis and both intergroup and interindividual variability can be examined. Multilevel studies thus provide an opportunity to link traditional ecological and individual-level studies. Multilevel models allow investigation of a variety of interrelated research questions. They allow separation of the effects of context (i.e. group characteristics) and of composition (characteristics of the individuals in groups): do groups differ in average outcomes after controlling for the characteristics of individuals within them? Are group-level variables related to outcomes after controlling for individual-level variables? Multilevel models can also be used to examine the effects of individual-level variables: are individual-level variables related to the outcome after controlling for group-level variables? Do individual-level associations vary from group to group, and is this partly a function of group-level variables? Multilevel models also allow quantification of variation at different levels (e.g. within group and between group) (Merlo et al. 2006) and the degrees to which these sources of variation are 'statistically explained' by individual-level and group-level variables. For example, is there significant variation in group-specific intercepts or slopes (do τ_{00} and τ_{11} differ significantly from 0)? How does this variability change as individual-level or group-level variables are added? What percentage of the variability in individual-level outcomes is between and within groups?

Table 5.2.5 Types of study design used in public health based on unit of analysis, level at which variability is examined, and constructs most appropriately investigated

Type of study	Unit of analysis	Level at which variability is examined	Constructs investigated as potential 'causes' of variability	
			Group level	Individual level
Ecological	Groups	Groups (utility for interindividual variability limited)	Yes	Only group-level proxies
Individual level	Individuals	Individuals (utility for intergroup variability limited)	No (Yes in contextual)	Yes
Multilevel	Groups and Individuals	Groups and Individuals	Yes	Yes

The types of studies, the levels at which variability is examined, and the types of constructs which they are more suited to investigate are summarized in Table 5.2.5.

Challenges in multilevel studies

The investigation of the health effects of factors defined at multiple levels raises a number of conceptual and methodological challenges. A key requirement is to begin with a clearly articulated conceptual model of the levels and constructs most relevant to the health outcome being investigated. A multiplicity of different nested (or non-nested) groups or levels may be relevant for a particular research question. Specifying the relevant levels is part of the development of the theory that should precede the data collection and statistical analysis. An important methodological complexity is that the variance apportioned to a given level in multilevel models may be over- or underestimated if a relevant level is ignored in the analysis (Subramanian 2003). In addition, misspecification of the relevant level may result in incorrectly concluding that groups (or higher-level) effects are absent. For example, if the research question pertains to the impact of availability of healthy foods on diet, and neighbourhoods within a country are specified as the higher-level unit for which food availability is measured, the absence of an effect of neighbourhood food availability could be entirely consistent with a large effect of country-level food availability. The failure to include the country level in the analyses would lead the researcher to miss the country-level food availability effect (this situation is directly analogous to the inability of studies restricted to individuals from a single group to detect group effects (Schwartz and Carpenter 1999)).

The 'groups' relevant to a specific health outcome may be difficult to define (e.g. neighbourhoods) or have fuzzy and changing boundaries (e.g. friendship groups). Data is often unavailable for the theoretically relevant group of interest so a crude proxy is used (e.g. census tracts for neighbourhoods) (Diez Roux 2001, 2007; O'Campo 2003). This results in substantial misspecification

of the group and the group-level construct of interest. Whereas epidemiology has become very sophisticated at measuring individual-level attributes, the measurement of group level has only recently received comparable attention. In some cases the measurement of group-level constructs may be simple (e.g. the presence of a certain law), but in others (e.g. social capital, the structure of social networks, or features of neighbourhoods), it is not. In some cases relevant group-level constructs can be easily characterized using available data, for example, the presence of a certain type of tobacco legislation or the degree of income inequality. Other constructs (e.g. levels of social cohesion) may benefit from the use of surveys. Survey data can be aggregated to the group-level using empirical Bayes approaches to improve the measurement validity (Raudenbush and Sampson 1999; Mujahid et al. 2007). This approach also allows assessment of the measurement properties of the aggregated survey measure, including the agreement between respondents within a group and the reliability of the group-level measure for discriminating between groups (Raudenbush 2003; Mujahid et al. 2007). Other measures of group-level constructs may involve approaches that do not necessarily involve aggregation of individual measures (e.g. the structure of connections between individuals within a group or the use of 'geographic information systems' to develop measures of neighbourhood availability and accessibility of resources). The most appropriate measurement strategy will depend on the construct being assessed as well as practical issues regarding the availability of data.

Because group-level factors must ultimately affect individuals in order to influence health, their effects must necessarily be mediated through more proximate individual-level processes. At the same time, some individual-level factors may be confounders of group-level effects either because individuals are selected into groups based on their individual-level attributes (e.g. persons with low income are selected into disadvantaged neighbourhoods) or because individual-level factors and group-level factors are associated for other reasons (e.g. persons living in countries characterized by mass production of processed foods may also be less physically active). Indeed much of the effort in the estimation of group-level effects in multilevel studies goes into controlling appropriately for individual-level confounders of group effects (Duncan et al. 1998; Pickett and Pearl 2001). Residual confounding by mismeasured or unmeasured individual-level variables has long been a critique of studies of group effects (Hauser 1970; Diez Roux 2001; Oakes 2004). On the other hand, many of these individual-level factors may be mediators of group effects raising questions regarding whether or not group-level effects should be adjusted for these factors (Macintyre and Ellaway 2003). It has been noted that the use of multiple regression approaches to partition indirect and direct effects (e.g. the portion of a group effect that is mediated through a given variable and the portion that is not) may lead to incorrect conclusions regarding the presence and strength of direct effects (Robins and Greenland 1992; Cole and Hernan 2002). The extent to which the approach of estimating a direct effect by comparing a group-level effect before and after adjusting for a hypothesized mediator results in substantial bias is likely to vary from research problem to research problem depending on the extent to which adjustment for the mediator actually introduces substantial confounding by other unmeasured variables related to the mediator and the outcome (Blakely 2002;

Blakely et al. 2013). An additional analytical complexity arises in longitudinal analyses where a given individual-level variable can be both a mediator and a confounder of the neighbourhood effect (because it is affected by prior neighbourhood conditions and in turn influences subsequent exposure to certain neighbourhood conditions). Special methods such as marginal structural models have been developed to estimate the causal effects under these circumstances (Robins 1989; Robins et al. 2000). The extension of these emerging methods to multilevel data structures has grown in recent years (Cerdá et al. 2010; Nandi et al. 2010). Recent work has also extended multilevel analytical strategies to account for other dependencies in the data such as those generated by spatial autocorrelation (Verbitsky and Raudenbush 2009).

Observational multilevel studies face the same problems as other observational studies in estimating causal effects from observational data. The ability to draw causal inferences is based on the extent to which the methods used approximate the counterfactual comparison of interest. One important limitation of past work in this regard especially prevalent in research on neighbourhood health effects has been the reliance on group-level derived variables (e.g. neighbourhood mean income) as proxies for the relevant integral group-level variable of interest (Diez Roux 2001; Pickett and Pearl 2001; Macintyre et al. 2002). This has limited the extent to which the data available allow researchers to approximate the counterfactual contrast of interest, even within the limitations of observational studies. Better specification of the group-level factors of interest (e.g. moving from crude proxies to measures of the specific constructs of interest) and the testing of specific hypotheses improve the ability to draw causal inferences.

The extent to which group-level effects can be validly estimated through the use of multiple regression methods (including multilevel models) to control for individual-level confounders has been questioned (Oakes 2004). The adjusted comparison requires assumptions regarding the effects of the individual-level variable on the outcome across groups, and may involve extrapolations beyond the support in the data if there is little overlap in the distribution of the individual-level variable across groups (e.g. individual-level income across levels of neighbourhood disadvantage). The extent to which this is a problem is an empirical question and may vary from research problem to research problem (Diez Roux 2004). This is no different from similar situations involved in adjusted comparisons in individual-level studies. Propensity score matching (Rubin 1997), which has been increasingly used in multilevel contexts, is one way to ensure that inferences are well supported (Harding 2003; Subramanian et al. 2007) although it has its own set of limitations related to generalizability of the results and also assumes no unmeasured confounding.

Another complexity in observational studies of group effects is that certain group-level properties may be at least partly endogenous to the characteristics of the individuals that make up the group (Subramanian 2003; Oakes 2004). This makes the identification of these group-level effects from observational data problematic. The extent to which group-level properties are endogenous to individual-level properties is likely to vary for different group-level constructs and different research questions (Diez Roux 2004; Subramanian 2004). Endogeneity may appear more of a problem in the case of derived group-level variables (e.g. mean neighbourhood income) that are constructed by aggregating the characteristics of individuals within a group. However, as

noted above, these variables are often used as proxies for a more clearly exogenous integral group-level property. Endogeneity is also a possibility for some integral group-level variables (e.g. dietary habits of residents may influence neighbourhood availability of healthy foods). However, it is unlikely that all group-level attributes are fully endogenous to the individual characteristics of persons of which the group is composed. Strategies to at least partly deal with the problem of endogeneity in the multilevel context have been proposed (Subramanian 2004) but in situations where endogeneity is a major concern other analytical strategies more appropriate for the analysis of dynamic systems may be more appropriate (Auchincloss and Diez Roux 2008).

Finally, sample size and power calculations in multilevel studies are complex and remain an area of active research (Raudenbush and Liu 2000; Raudenbush and Bryk 2002; Hox 2010; Snijders and Bosker 2011; Myers et al. 2012). In general, the power for estimating the individual-level regression coefficients depends on the total sample size (Hox 2010). The power for higher-level (group-level) effects and cross-level interactions (interactions between group and individual-level variables) depends more strongly on the number of groups than on the total sample size (Hox 2010). However, the power to estimate the ratio of between-group to total variability (the intraclass correlation coefficient) is affected by the number of groups and the number of persons per group in a different manner than the power to detect associations of group-level variables with individual-level outcomes (the fixed effects of group properties) (Snijders and Bosker 2011). Power and sample size calculations need to specify the key multilevel parameters of interest, and trade-offs may be involved.

Conclusion

In public health research, both predictors and outcomes may be conceptualized at different levels of organization, and understanding outcomes at a given level may require taking into account information pertaining to levels above or below it. Each system can be thought of as nested within another level, and dynamically interrelated with the levels above and below it. In addition, each level may acquire 'emergent' properties, unique characteristics confined to that level, which are different to the properties of its components. The selection of the appropriate study design should be based on the specific research question investigated, including the level of organization about which inferences are to be made, as well as the levels of organizations of the constructs of interest (including the main independent variables as well as potential confounders or effect modifiers of the association).

Problems related to the use of ecological studies and ecological variables in epidemiology often result from confusion regarding the level of organization to which the research question pertains, the level of organization at which the constructs of interest are defined and measured, and the sometimes inappropriate use of variables defined and measured at one level to proxy constructs defined at another level. Of course researchers must necessarily focus on certain aspects of the continuum of levels of organization and not all studies need (or can) span all levels. Rather than defending or critiquing one study design in favour of another, it is more useful to evaluate whether the level of analysis investigated and the constructs examined are appropriate for the specific question being asked. Because 'ideal' study designs are often not

possible, the key lies in determining whether the particular design employed is 'good enough' for the question being asked. The issues reviewed in this chapter may be helpful in making this judgement.

Cross-sectional studies

Manolis Kogevinas and Leda Chatzi

Introduction to cross-sectional studies

Cross-sectional studies examine the relationship between diseases (or other health-related characteristics) and other variables of interest as they exist in a defined population at a particular point in time (Last 2001). They could be defined as studies taking a snapshot of a society. Synonyms used for cross-sectional include prevalence studies and disease frequency studies.

The principal characteristic of cross-sectional studies is that they provide information on the *prevalence* of disease, that is, they include prevalent cases. In cross-sectional studies, exposure and disease are measured at the same point in time but this characteristic is shared by other epidemiological designs, for example, case-control studies. In many cross-sectional studies information on past exposures is not collected but this should not be regarded as a characteristic defining these studies. The outcome measured in cross-sectional studies can be a continuous variable such as blood pressure or forced expiratory volume in 1 second (FEV₁), as compared to a dichotomous outcome measured in case-control studies and, in most occasions, in cohort studies.

As is frequently the case in epidemiology, studies may use mixed designs. For example, a cross-sectional study may measure a biomarker referring to current exposure (e.g. vitamin E), may request information for the past (e.g. use of health services the last year), may identify older and recent cases (e.g. subjects having had asthma in childhood or those having their first attack of asthma in the last few months), and may convert into a cohort study if subjects included in the cross-sectional studies are followed up. The statistical analysis of cross-sectional studies depends on their hybrid design and is frequently similar to that of a case-control study using logistic regression and calculating (prevalence) odds ratios. Cross-sectional studies are extensively used to measure the prevalence of disease, exposures, or other health-related variables. On these occasions, the representativeness of the studied sample is a prerequisite.

In this chapter we will first describe the uses of cross-sectional studies in epidemiological and public health research and then discuss methodological issues concerning the design, the main biases of these studies including response rates, and how to improve participation in the studies. We will finally discuss issues related to the statistical analysis of cross-sectional studies. Many of these issues are also relevant to other epidemiological designs.

Uses of cross-sectional studies

Cross-sectional studies have been used to evaluate the prevalence of diseases and of health-related variables and also to

evaluate the aetiology of diseases. Large, multipurpose, national cross-sectional studies are conducted in several countries for administrative reasons and to provide background documentation on the health status of a population.

National multipurpose surveys

National (or regional) multipurpose surveys are carried out routinely or ad hoc in several countries. The purpose and themes of these surveys are multiple and they may cover different health problems in successive years. The Health Survey in England collects data from a representative sample of approximately 8000 adults aged 16 and over and 2000 children in England (Department of Health 2012). Each year the survey consists of a series of core elements and also includes special topics. In 2012 the core survey covered general health, smoking, drinking, fruit and vegetable consumption, height, weight, blood pressure measurements, and collected blood and saliva samples. Special topics included were cardiovascular disease, hypertension, diabetes, social care, drinking, chronic pain, adult and child obesity, and information on well-being and dental health.

The National Health and Nutrition Examination Survey (NHANES) in the United States is the largest national multipurpose survey and is conducted on a routine basis (Centers for Disease Control and Prevention 2014). The NHANES is a programme of studies designed to assess the health and nutritional status of the civilian, non-institutionalized population of the United States. The survey examines a nationally representative sample of about 5000 persons each year and combines interviews and physical examinations.

Results of national health surveys can be used for several purposes, such as the evaluation of the prevalence of health-related behaviours or of symptoms, time trends in risk factors or health symptoms, the identification of causes of disease, and evaluation of health needs. Changes of health problems and risk factors in the population over time can be identified through repeated surveys. Repeated national multipurpose surveys may examine a sample of the same population, but not intentionally the same individuals. Thus, they are particularly useful for assessing changes in the same community, state, or nationally which may have undergone changes due to other factors, such as access to healthcare or population mixes. This type of information may allow health planning through the identification of needs and effectiveness of existing policies and interventions. Time trends in obesity and in levels of toxic substances such as lead in blood are examples of the use of these types of surveys. The prevalence of overweight and obesity has increased in recent years in both children and adults in many countries. Time trends and the effect of socioeconomic status

on childhood obesity in the United States were examined using data from two large, nationally representative health surveys and data systems: the 1976–2008 National Health and Nutrition Examination Surveys (NHANES) and the 2003 and 2007 National Survey of Children's Health (NSCH) (Singh and Kogan 2010). The prevalence of overweight and obese children increased significantly in relation to decreased levels of household education and income in both 2003 and 2007 (Fig. 5.3.1). The prevalence of obesity for children with parents having fewer than 12 years of education was 30 per cent in 2007 compared to around 10 per cent for children whose parents had a college degree. The socio-economic health disparities became wider in the period examined (Fig. 5.3.1).

The existence of a large national database has several advantages for the identification or confirmation of risk factors of a disease. Problems of cross-sectional studies that evaluate risk factors of diseases are discussed in the next section and particularly potential biases from the inclusion of prevalent cases and from frequent lack of information on past exposures. However, the evaluation of a national representative population sample, as is the case in several multipurpose surveys, has the advantage of capturing a global image of the society including population groups that may be omitted in other types of design. An example provided here is of a study on cleaners based on NHANES. The importance of this study lies, among others, in the fact that domestic cleaners are a population group that is very hard to identify through the usual designs applied, that in this case of occupational asthma would be industry-based cohorts.

Information on the population distribution of health problems and risk factors, provide important clues to researchers on

the causes of disease and also may confirm previous hypotheses in large population samples. Arif and colleagues used data from the Third National Health and Nutrition Examination Survey (NHANES III) 1988–1994, to evaluate associations between occupation and work-related asthma and work-related wheezing among US workers (Arif et al. 2003). They identified several occupations that were at risk of developing work-related asthma with cleaners and equipment cleaners showing the highest risks. The population attributable risk for work-related asthma was 26 per cent. The study confirmed a previous hypothesis on asthma in cleaners (Kogevinas et al. 1999), provided an evaluation of asthma risk in other occupations in the US population, and also gave an estimate of the burden of occupational asthma.

By identifying the healthcare needs of the population, government agencies and private sector organizations can establish policies and plan research, education, and health promotion programmes that will help improve present health status and prevent future health problems.

Studies examining the prevalence of disease

Cross-sectional studies are, by definition, the appropriate design to evaluate the prevalence of diseases. An evaluation of the prevalence of a disease may be performed for administrative purposes or for reasons related to the evaluation of aetiological factors. The main issues regarding the conduct of these studies include the representativeness of the sample, the size of the sample, and the measurement of outcomes and exposures. The International Study of Asthma and Allergies in Childhood (ISAAC) is among the largest cross-sectional studies ever done.

The ISAAC study was designed to allow comparisons of the prevalence of allergic disorders in childhood between populations in different countries and their trends over time (Asher et al. 1995). In the early 1990s although it was generally perceived that asthma prevalence was increasing there existed very limited population-based estimates. The study included simple 'core' instruments for measuring the prevalence of allergic disorders, suitable for different geographical locations and languages: (1) written questionnaires on the prevalence and severity of asthma, rhinitis, and eczema for self-completion in 13–14-year-olds, or for completion by parents of 6–7-year-olds; and (2) video questionnaires on the prevalence and severity of asthma for self-completion by 13–14-year-old children. In phase I, children aged 13–14 years were studied in 155 centres in 56 countries ($n = 463,801$) and children aged 6–7 years were studied in 91 centres in 38 countries ($n = 257,800$) (Anonymous 1998). Up to 20-fold variations in the prevalence of 'current wheeze' (in the last 12 months) were observed between centres worldwide (range 1.8–36.7 per cent), with a sevenfold variation observed between the 10th and 90th percentiles (4.4 per cent; 30.9 per cent). The highest 12-month period prevalences were from centres in the United Kingdom, Australia, New Zealand, and the Republic of Ireland; the lowest prevalences were from centres in Eastern Europe, Albania, Greece, China, Taiwan, Uzbekistan, India, Indonesia, and Ethiopia.

Aetiological research

Cross-sectional studies are particularly valuable for the investigation of the aetiology of non-fatal diseases, degenerative diseases, diseases with no clear point of onset, for example, chronic

Fig. 5.3.1 Trends in the prevalence of overweight and obese children aged 10–17 years by parental education, United States, 2003–2007.

Reproduced from Singh, G.K. and Kogan, M.D., *Childhood Obesity in the United States, 1976–2008: Trends and Current Racial/Ethnic, Socioeconomic, and Geographic Disparities: A 75th Anniversary Publication*, Health Resources and Services Administration, Maternal and Child Health Bureau, Department of Health and Human Services, Rockville, Maryland, USA, 2010, available at: http://www.hrsa.gov/healthit/images/mchb_obesity_pub.pdf.

bronchitis, and effects on physiological variables, for example, forced vital capacity (FVC) or liver enzyme levels. In diseases with no clear point of onset it is difficult to identify incident cases and conduct cohort or incident case–control studies. The prevalence of a disease will be highest if it occurs relatively frequently and if the disease persists in time. A disease could be described as persistent if it is not rapidly fatal and if it does not usually manifest as a transitory condition. Diseases such as asthma and osteoarthritis that have a relatively high prevalence have frequently been examined in cross-sectional studies.

The European Community Respiratory Health Survey (ECRHS) is in many aspects similar in design to ISAAC and was initially conducted as an international cross-sectional study enrolling young adults mainly from European centres to evaluate the prevalence and aetiology of asthma and related diseases (Burney et al. 1994). In an initial screening short questionnaire, the ECRHS included information from around 140,000 individuals from 22 countries. A subsample of the study incorporated extensive questionnaires, measurement of atopic markers, spirometry, and methacholine challenge. The key findings of the study are the large geographical differences in the prevalence of asthma, atopy, and bronchial responsiveness in adults, with high prevalence rates in English-speaking countries and low prevalence rates in the Mediterranean region and Eastern Europe. Analyses of risk factors have highlighted the importance of occupational exposure for asthma in adulthood (Kogevinas et al. 1999). The association between sensitization to individual allergens and bronchial responsiveness was strongest for indoor allergens (mite and cat). Analysis of treatment practices has confirmed that the treatment of asthma varies widely between countries and that asthma is often undertreated (Janson et al. 2001). Subjects were subsequently followed up and the study was converted into a prospective study including subjects with and without asthma at the initial contact.

Design of cross-sectional studies

Main design issues in cross-sectional studies

The simplest form of a survey in a population is a one-time measurement of the prevalence of a disease (Checkoway et al. 2004). On some occasions, repeated surveys (panel studies) are conducted on the same or different individuals.

When evaluating the prevalence of a disease the sample studied should be representative of the base population from where subjects are recruited (internal validity). The random error of an estimate depends directly on the size of the study and standard techniques exist to calculate this error (see, e.g., free software such as Epi Info™ (Centers for Disease Control and Prevention (2013))). The measurement of outcomes may be particularly complicated since frequently prevalence studies are conducted for diseases that have a gradual onset and that are not fatal. In addition, problems may occur when comparisons of prevalence are done between countries that may have different systems for the identification of the disease or even different perceptions and oral descriptions of a disease. An example of this refers to the large prevalence studies conducted for the evaluation of the prevalence of children's asthma such as the ISAAC study (see earlier description). Wheezing is a key symptom defining asthma in childhood. However the perception of what is wheezing is not necessarily the same in different

countries and, further, some languages do not have a single word to describe what in English is called 'wheezing'.

Generalizability is another aspect of representativeness and refers to whether the findings in one population can be extrapolated to other populations (external validity). Generalizability is less of a problem when examining risk factors of disease since biological mechanisms through which an agent may provoke disease tend to be similar between populations. Generalizability may be, however, more difficult to ensure when examining prevalence since this may vary considerably within and between populations and extrapolations from one population to another can be problematic.

Panel studies apply a hybrid design that combines cross-sectional and cohort study methods. They are series of cross-sectional studies performed over time on the same group of individuals (measuring, however, prevalence rather than incidence), or in different groups of a population in subsequent time periods. The objective is to evaluate change in health status in relation to changes in exposure. Small groups, or panels, of individuals are followed over short time intervals, and health outcomes, exposure, and potential confounders are ascertained for each subject on one or more occasions. This design is especially useful for the study of physiological variables (i.e. pulmonary function, blood pressure), for which changes over several years may indicate early stages of disease processes. It is also useful to evaluate time trends in a disease.

The third phase of the ISAAC study (ISAAC, phase III) could be regarded as one form of a panel study. ISAAC-III was a repetition of the phase I survey after 5–10 years to examine time trends in the prevalence of allergic disorders in the same ages in centres and countries that participated in ISAAC phase I. The findings from ISAAC phase III indicate that international differences in asthma symptom prevalence have reduced with decreases in prevalence in English-speaking countries and Western Europe and increases in prevalence in regions where prevalence was previously low (Fig. 5.3.2). Although there was little change in the overall prevalence of current wheeze, the percentage of children reported to have had asthma increased significantly, possibly reflecting greater awareness of this condition and/or changes in diagnostic practice. The increases in asthma symptom prevalence in Africa, Latin America, and parts of Asia indicate that the global burden of asthma is continuing to rise, but the global prevalence differences are lessening (Pearce et al. 2007).

Panel studies may also evaluate the same individuals before and after an intervention or an exposure. These types of studies have been extensively used in occupational and environmental epidemiology to evaluate changes in symptoms or physiological parameters following an intervention in a workplace or in the general environment such as air pollution. An example is a study that examined the effects of short-term exposure to diesel traffic in 60 adults with asthma (McCreanor et al. 2007). Each participant walked for 2 hours along Oxford Street in London (United Kingdom) and, on a separate occasion, through Hyde Park, London. Physiological and immunological measurements were performed after each occasion. It was found that walking for 2 hours on Oxford Street induced consistent reductions of up to 6.1 per cent in FEV₁ and up to 5.4 per cent in FVC that were significantly larger than the reductions in FEV₁ and FVC after exposure in Hyde Park. Similar changes were also observed for markers of inflammation in the lungs.

Fig. 5.3.2 Ranking plot showing the change per year in prevalence of current wheeze (wheeze in the past 12 months) in children aged 13–14 years for each centre by country, ISAAC-III study.

Reproduced from Pearce, N. et al., Worldwide trends in the prevalence of asthma symptoms: phase III of the International Study of Asthma and Allergies in Childhood (ISAAC), *Thorax*, Volume 62, Issue 9, pp. 758–66, ©2007, with permission from BMJ Publishing Group Ltd.

Panel studies, particularly when examining the same individuals, could be regarded as prospective studies and frequently this distinction between study designs is blurred. The study in Oxford Street is a cross-over study that includes aspects of a prospective experimental design and aspects of a cross-sectional study. The main difference between cross-sectional panel studies and prospective designs is that panel studies examine the prevalence of a disease or a physiological parameter rather than incidence.

Sampling and response rates

Cross-sectional studies aiming to identify the prevalence of a specific factor in a community should select a representative sample of that community. The same is, in principle, desirable in cohort and case-control studies but in these studies the main issue is internal validity rather than external validity (generalizability representativeness). In cohort studies the most important issue concerning subject selection and validity of results is completeness of follow-up. In case-control studies the crucial issue concerning selection of subjects is that cases and controls should be selected from the same study base; whether cases are representative of the general population is, by contrast, not crucial for the internal validity of a case-control study.

In a cross-sectional study, however, representative sampling is the only procedure that allows selection of subjects in a population that can be used as the basis of generalization. A sampling frame should be identified that allows the identification of any subject in a population that could be included in a sample. Different methods can then be applied to select the subjects. Sampling error estimation has been exhaustively addressed in statistics. This depends on the number of subjects included in a study and can be estimated. Non-sampling error refers to bias, and may be of considerably higher importance than sampling error. Enlarging the sample does not reduce non-sampling error. Non-response may be non-random and may, therefore, be related to factors of interest for a study such as education, ethnicity, or obesity.

Response rates and dealing with non-response

A response rate of 60 per cent has been frequently accepted as an adequate response in population surveys. However, the issue of non-response is complex and the acceptance of a fixed percentage as an adequate and probably unbiased response rate is an oversimplification. To some extent, this seems similar to the arbitrary acceptance of $p < 0.05$ as the level for statistical significance (Timothy et al. 2012). There is a general perception, not only among epidemiologists, that it is becoming increasingly difficult in many industrialized countries to achieve high response rates in surveys (Hartge 2006). In an evaluation of 355 original epidemiological papers published in ten high-impact journals, it was found that average participation in epidemiological studies has fallen in the last 30 years and this has particularly affected controls in population-based studies (Morton et al. 2006). At least some information regarding participation was provided in 59 per cent of cross-sectional studies, 44 per cent of case-control studies, and 32 per cent of cohort studies. In 51 out of 86 cross-sectional studies that reported response rates, the mean participation was 74 per cent, ranging from 28 per cent to 100 per cent. In recent years, response rates among population controls of around 50 per cent are not uncommon. Participation in cross-sectional studies decreased by approximately 1 per cent per year from 1970 to 2003 (Morton et al. 2006).

The use of telephones as a means for defining a sampling frame has been rapidly decreasing. The main assumption for the use of random digit dialling (RDD) was that there was one working residential phone number per household. This assumption is no longer valid due to rapid changes in telecommunication, particularly the use of mobile phones. The rapid increase in the use of mobile phones throughout the world has made nearly impossible the identification of a roster of phones identified to a specific area through which a sample could be derived. In addition, in several countries the use of telephone contacts for commercial reasons has resulted in a decrease of response rates to any such type of contact. Computer-assisted telephone interviews are, however, an equally valid and efficient means of collecting information among subjects that have been contacted and agreed to participate.

Studies collecting biological samples

In recent years an increasing proportion of epidemiological studies collect biological samples, following the advances in molecular and genetic techniques and their application in large-scale

studies. A recent review of 355 studies identified very high participation rates (above 90 per cent) in cohort and cross-sectional studies collecting biospecimens. However, only about a third of the studies reporting collection of biospecimens also reported response rates for the biological samples. A total of 134 of 355 (38 per cent) articles reported the collection of biological specimens to measure exposure or disease and the proportion of cohort and case-control studies that collected biological specimens increased over time while that of cross-sectional studies remained fairly constant (Morton et al. 2006). Large cross-sectional studies, such as the NHANES, are regularly collecting biological samples and the inclusion of the collection of biospecimens does not appear to influence the representativeness of the sample.

An increasing number of studies are collecting saliva or other biospecimens by mail. Several studies that have collected saliva samples by mail have obtained response rates that are not very different from those observed for paper-and-pencil questionnaires. In a study on 2994 subjects at Geneva University, Switzerland, the response rate for subjects requested to provide a mail questionnaire and saliva was 52 per cent while for those requested to complete only the mail questionnaire, it was 63 per cent; using financial incentives increased the response rates by 6–11 per cent (Etter et al. 2005). Sociodemographic factors may affect response rates in such a type of sampling. Self-collection of saliva was evaluated, concerning both response and quality of DNA retrieved in a random sample of 611 men (ages 53–87 years) in Sweden (Rylander-Rudqvist et al. 2006). The response rate was 80 per cent and varied from 89 per cent for those aged 67–71 years to 71 per cent in those aged 77–87 years. Similar to other studies, the DNA extracted was of high quality and could be used as an alternative to blood DNA in molecular epidemiological studies. There is little empirical evidence in several cultures to evaluate general tendencies concerning participation when biospecimens are collected. Whether non-response may differentially affect the analysis of biomarkers is unknown.

Fig. 5.3.3 Effects on questionnaire response (odds ratios and 95 per cent confidence intervals) of eight strategies where combined trials included over 1000 participants.

Source: data from Edwards, P. et al., Increasing response rates to postal questionnaires: systematic review, *British Medical Journal*, Volume 324, p. 1183, © 2002 BMJ Publishing Group Ltd.

One study examined a series of genetic data (polymorphisms, haplotypes, and short tandem repeats) from 2955 individuals of three studies and found no evidence of differential results by participation (Bhatti et al. 2005). A note of caution, however, has been made against assuming that willingness to participate should not vary with a particular polymorphism or other forms of genetic variation (Hartge 2006).

Improving non-response

The difficulties in achieving high response rates and the potential biases resulting from self-selection makes indispensable the understanding of the reasons for non-response and the application of methods for limiting non-response. Numerous studies have evaluated factors affecting non-response in epidemiological and other types of studies. Most of the factors frequently identified such as age, sex, education, exposure status, method of recruitment, and type of questionnaire used may also be culture specific. This indicates that, in addition to some general guidelines, there is a need to verify main approaches to increase response in different sociocultural settings, and these may change in different time periods. Nevertheless, some general guidelines can be drawn up based on numerous observational and on randomized trials.

A comprehensive systematic review of available randomized trials from any relevant discipline (not restricted to medicine or epidemiology) evaluated factors that influence response to postal questionnaires (Edwards et al. 2002). Information from 292 randomized controlled trials that included 258,315 participants was reviewed. A total of 75 strategies that could influence response to postal questionnaires were reviewed. The review identified questionnaire length, use of monetary incentives particularly when not conditional on response, appearance of the package, layout of the questionnaire, type of follow-up, and registered delivery as the most influential factors in terms of participation rates. Fig. 5.3.3 shows effect estimates for the most influential factors. Contacting participants before sending questionnaires increased response as did follow-up contact. Questionnaires designed to be of more interest to participants were more likely to be returned but questionnaires containing questions of a sensitive nature were less likely to be returned. Questionnaires originating from universities were more likely to be returned than were questionnaires from other sources, such as commercial organizations. Overall, response to postal questionnaires can be improved by following strategies shown to be effective in other research.

Adjusting for non-response

The most important measure to deal with potential biases from non-response is to minimize, as much as possible, the number of non-responders. As already discussed, this is done through selecting adequate ways of contact and through repeated contacts with subjects. Several approaches have been described to evaluate and adjust estimates of prevalence taking into account non-response.

An evaluation of basic characteristics of non-responders is important and may give clues concerning the representativeness of the sample. Such characteristics may be derived from information known for the target population from other surveys, for example, percentage of smokers. They can also be derived from a subsample of non-responders followed up intensively. Estimates of prevalence can then be weighed using the data of respondents but

taking into account information on variables known for responders and non-responders such as age, sex, residence, etc.

A usual procedure in prevalence surveys is to perform repeated contacts of subjects to increase response rates. The final estimates are derived from the total number of responders. In an alternative procedure it can be assumed that responders at different mailings or contacts are not representative of the population. Under this assumption, the overall prevalence estimates are modelled using the prevalence of each mailing. A cumulative response at the time of each mailing can be calculated taking into account different covariates (e.g. age, sex) of the samples responding in each mailing, and estimates of the prevalence of non-responders are derived through extrapolation.

Such modelling was conducted analysing responses of 13,007 subjects in the three English centres of the European Community Respiratory Health Survey (Chinn et al. 1995). Modelling responses to take into account centre, age, and sex had only small effects on estimated prevalence. For example, in Norwich, out of 440 eligible individuals aged 20–24 years, 141 responded to the first mailing (32 per cent), 58 to the second (cumulative response 45.2 per cent), and 45 to the third mailing (cumulative response 55.5 per cent). Prevalence of wheezing was modelled taking into account differences among responders and non-responders by age and sex and this gave an estimated prevalence of wheezing of 25.7 per cent. This estimate was further examined through modelling. In a model that included a parameter for a linear trend in prevalence with each mailing by age and sex group, an overall prevalence of 23.9 per cent was estimated. Overall in this study although several models gave statistically significant differences, in absolute terms the estimates of prevalence derived were rather similar. Such type of modelling is useful to explore the sensitivity of estimated prevalence to non-response bias. However, frequently changes due to such modelling are small and, in general, caution should be exerted when applying such models. In conclusion, the best way of adjusting for non-response is not having much of it.

Item non-response

Apart from the overall response rate the quality of the answers of participants deserves attention as well. The issue of item non-response has been little discussed and usually not reported. What is usually discussed and reported as ‘non-response’ refers to the non-contact with a selected person or the refusal of this person to participate (unit non-response). Failure of a responder to answer an individual question or provide a sample (item non-response) should also be considered and can equally affect the representativeness of specific analyses in a study. In a study on bladder cancer in Spain, the overall response rate to the main questionnaire was 85 per cent. However, the response to specific items was lower. For example, the questions on lifetime consumption of water and complete information on water quality in each of the residences of the subjects were available for 1479 out of a total of 2490 subjects (Villanueva et al. 2007). An evaluation of differences in sociodemographic characteristics of subjects included or excluded from the water analyses and also differences in the prevalence of known risk factors such as smoking indicated that on this occasion item non-response was not likely to bias results. Exclusion of subjects reduced, however, the statistical power of the study.

The inclusion of several variables in an analysis may result in a large amount of missing data due to item non-response. The

pattern of missing data should be examined and, if possible, the causes of missing information determined. Multiple imputations methods are increasingly used to improve efficiency and minimize selection bias. It is frequently assumed that data are missing at random although this is not always easy to identify. Missing values are imputed and a set of complete data sets is generated that are further analysed individually to obtain a set of parameters and then combined into overall estimates (Rubin 1987). Several methods have been proposed to impute missing data and modern software has simplified the analysis of multiply imputed data (White et al. 2011; Cummings 2013).

Sampling methods

Different types of sampling may be applied in cross-sectional studies depending on the aims of the study, characteristics of the population studied, the available background information, and the means available in each study.

In a simple random sample, all subsets of the sampling frame are given an equal probability of being selected. What is used most frequently in large surveys is stratified sampling: this involves a first-stage selection of different categories of the population and subsequent selections at random within each stratum. The main reason for doing stratified sampling is efficiency, so as to secure adequate sampling of small population groups and avoid oversampling of larger groups. Several other probabilistic or non-probabilistic types of sampling have been applied such as ‘cluster sampling’ in which the unit selected is a group of persons (e.g. a city block) rather than individuals, and ‘snowball sampling’ and ‘respondent-driven sampling’ where a first set of study subjects (‘seed participants’) is used to recruit more subjects into the sample. These latter types are convenience sampling methods that are applied when a complete identification of the primary sampling population is not possible or hard to find (Magnani et al. 2005). Respondent-driven sampling is a variation of snowball sampling that allows a better control of the selection of the population examined, mainly by collecting information from recruiters on the size of their social network and on also on persons approached but who did not participate. The availability of such information, however, does not secure the selection of a random sample from members of a network (Heimer 2005). In addition, respondent-driven sampling is believed to have higher external validity than other convenience sampling methods because it may extend better to all potential members of a network (Magnani et al. 2005). The same approach has been used for the identification of samples for interventions in hard-to-reach populations. For example, respondent-driven sampling was used in a cluster-randomized trial in India to assess the effectiveness of HIV counselling and testing among men who have sex with men (Solomon et al. 2013).

Snowball sampling was applied in a study on the prevalence of depression among female sex workers of eastern Nepal (Sagtani et al. 2013). Snowball sampling is especially useful when the objective is to reach populations that are inaccessible or hard to find. The participants were 210 female restaurant-based and street-based sex workers in five cities of eastern Nepal. In countries like Nepal where commercial sex is illegal, the criminalized status of their work means that commercial sex workers are prone to harassment and violence. Under such conditions, identifying a base population and sampling from this population is impossible. Sex workers

were contacted through snowball sampling. The first few respondents were traced with the help of a non-governmental organization working on HIV prevention in the study area. Face-to-face interviews were conducted and additional respondents were nominated. The prevalence of depression among respondents was 82 per cent. A major limitation of this type of sampling is that external validity of the study is questionable due to the unknown sampling frame.

Biased samples are samples where some members of the population are less likely to be included than others. (Note that some stratified samples are deliberately biased but the degree of bias can be estimated.) There are several classic examples of biased sampling. Among the most well known is a large opinion poll in the US presidential election in 1936 that erroneously predicted that the incumbent president, Franklin Roosevelt, would lose by a large margin. This poll of approximately 2 million persons was based on people who were readers of a magazine, supplemented by records of registered automobile owners and telephone users. The error was produced because the sample overrepresented more affluent people who were less likely to vote for the Democratic candidate.

Examples of different sampling procedures are listed in the following paragraphs, namely sampling in a large multipurpose survey (NHANES) in the United States, a large international prevalence survey (ISAAC), together with a local survey of a difficult-to-identify population of drug addicts in Spain.

The NHANES survey in the United States applies a multistage (four stages) probability sampling to select participants representative of the civilian, non-institutionalized US population (Centers for Disease Control and Prevention 2014). In stage 1, primary sampling units (mostly single counties) are selected. In the second stage, these units are divided up into segments (generally city blocks) and sample segments are selected taking size into account. In stage 3, households within each segment are listed and a sample is randomly drawn. In the final stage, individuals are randomly chosen from a list of all persons residing in the selected households within designated age–sex–race strata. NHANES is designed to sample larger numbers of certain subgroups of particular public health interest including African Americans, adolescents, and others.

In ISAAC, a combination of non-random and random methods was used. The areas participating within each country were not selected at random but instead qualitative criteria and convenience sampling were used. Stratified random sampling was then used within a given geographical area to select the school children. All schools in each geographical area centre were listed and a random sample was selected. The sampling unit was the school and non-participating schools were replaced. All children on a selected school within the two specified age groups (6–7 and 13–14 years of age) were included.

Web-based research and the use of wireless technologies

Web-based research has been expanding in recent years. The Internet has been used in research and clinical settings to enhance contact with participants. Prevalence surveys have traditionally been based on self-administered paper questionnaires, face-to-face or telephone interviews. Internet surveys have been proposed as having advantages compared to traditional approaches, for example, face-to-face or telephone interviews, regarding turnaround time and expenses. Internet-based surveys

similar to computer-assisted personal or telephone interviews have advantages concerning data management as compared to paper-and-pencil questionnaires.

The two main issues regarding the validity of use of Internet surveys are response rates and quality of the data collected. Several studies that focused on specific population groups with high indexes of Internet use have found comparable response rates between Internet-based questionnaires and more traditional approaches (Pealer et al. 2001). However, many of these studies report response rates for populations recruited through the Internet rather than for population-based samples. These results are therefore difficult to generalize, although they indicate that in specific populations, Internet-based surveys provide high-quality data.

Few studies exist that compare population-based data using both Internet and traditional type approaches. Results differ and depend crucially on the degree of education and computer literacy in different cultures, ages, and sociodemographic groups. Women referred for mammography at a Danish public hospital aged less than 67 years and without a history of breast cancer, were randomized to either receive a paper questionnaire, with a prepaid return envelope, or a guideline on how to fill in the Internet-based version online (Kongsved et al. 2007). The response rate was 18 per cent for the Internet group compared to 73 per cent for the paper questionnaire. An interesting aspect of this study was that after sending a reminder and offering the possibility of using the alternative questionnaire form (i.e. a paper questionnaire in the Internet group), the response rate for the Internet group became comparable to that of the group assigned the paper questionnaire. In the Millennium cohort (Smith et al. 2007) of military personnel in the United States, a similar proportion of the approximately 70,000 responders chose to respond using the Internet. Web responders were more likely to be male, to be younger, have a higher education, work in technical occupations, to be obese, and to smoke more cigarettes. They were less likely to be problem alcohol drinkers and to report occupational exposures. Several studies have evaluated quality of information from web-based studies and have found that it is similar to, if not better than, self-administered questionnaires. In the Danish mammography study mentioned earlier (Kongsved et al. 2007), the quality of the information was better in the Internet version with 98 per cent having no missing data compared to 63 per cent filling in a complete paper questionnaire. A study in Sweden (Bonn et al. 2013) compared web-based self-reports of bodyweight with weight measured at the study centre in a convenience sample of 149 individuals. As frequently happens with self-reported weight, overweight subjects (body mass index ≥ 25 kg/m²) tended to underreport their weight and the overall mean difference between self-reported and measured weight was -1.2 kg. The Spearman correlation coefficient, however, between self-reported and measured weight was 0.98 ($P < 0.001$) indicating that self-reported weight and perhaps other anthropometric measures via the web can be a valid method of data collection.

The use of wireless technologies and devices is rapidly increasing and it is expected that smartphone technology will become the most frequent way to access information in the World Wide Web. The ubiquity of mobile device ownership and the development applications allows new ways of contact and recording of health-related information in population studies. A study in

Barcelona used smartphone technology to improve environmental exposure assessment applying novel sensor technologies integrated with mobile phones (de Nazelle et al. 2013). Geographic location and physical activity patterns were tracked through a smartphone application in 36 subjects and were then linked to space–time air pollution mapping for improved air pollution exposure assessment. This information provides an accurate account of mobility of the subjects during the day and of physical activity. Mobile technologies also allow individuals to record and communicate behaviour in real time from any location. A study on 50 trained subjects evaluated the feasibility of using Twitter to capture dietary behaviour and reasons for eating over 3 consecutive days (Hingle et al. 2013). A list of hashtags representing food groups, for example, #fruit, and reasons for eating, for example, #mood, were provided to participants who were encouraged to annotate hashtags with photos, text, and links. A total of 773 tweets including 2862 hashtags were reported and eating behaviours were visualized through ‘maps’ of hashtag co-occurrences suggesting time-varying diet and behaviour patterns.

On the basis of existing evidence it appears that Internet-based surveys may provide high response rates in selected populations. In most general populations, however, Internet-based surveys do not yet seem to provide adequate response rates and this may lead to selected sampling. Several studies indicate that Internet surveys may be efficiently combined with traditional techniques to save resources and perhaps provide more complete answers. Clearly, more research is needed in the future in population-based surveys to evaluate changes in response in Internet-based research. While sensor-based applications in environmental epidemiology have been widely used and have been shown to improve exposure assessment, there is a lack of empirical evidence in public health research concerning the use of popular software applications such as Twitter.

Bias in cross-sectional studies

Cross-sectional studies may suffer from the same potential biases as other epidemiological designs: misclassification, selection bias,

and confounding. Issues of particular concern in cross-sectional studies are the potential biases from the mixing of incident and prevalent cases, the frequent lack of information on past exposures and consequently on the time sequence of events, and the lack of representativeness in studies evaluating the prevalence of disease or of other health-related variables. Because of these difficulties, it has been recommended that cross-sectional studies examining the risk factors of disease are appropriate for diseases that produce little disability, and are also appropriate to the presymptomatic phases of more serious disorders (Coggon et al. 1997).

Incidence–prevalence bias (known as Neyman bias; also discussed as length-bias) is a type of selection bias due to the mix of incident and prevalent cases in cross-sectional studies. Incidence–prevalence bias refers specifically to the selection of a case group that is not representative of cases in the community. Fig. 5.3.4 (left graph) shows the hypothetical time of occurrence of disease and the duration of disease. A cross-sectional study would include a disproportionately high percentage of cases with long duration while those with more aggressive disease and hence short duration would have a lower probability of being sampled. The latter is exemplified in Fig. 5.3.4 (right graph). A bias would occur if survivors of a condition studied are atypical with respect to the exposure evaluated. If the exposure examined is not directly or indirectly related to survival, inclusion of prevalent cases would not bias any association. In addition, as noted by Hill et al. (2003), for diseases with extremely low case fatality (e.g. rheumatoid arthritis), studies based on prevalent cases are not subject to Neyman bias even if the risk factor under study produces increased mortality from other causes.

The association of smoking with Alzheimer’s disease has been discussed as a potential effect of incidence–prevalence bias. Several cross-sectional studies have suggested that smoking exerts a protective effect on Alzheimer’s disease. Evidence, however, from a few cohort studies is controversial. A cross-sectional study that included a prospective component suggested that part of the protective effect could be attributed to Neyman bias, specifically because smokers with dementia could have worse survival than

Fig. 5.3.4 Incidence–prevalence bias in cross-sectional studies. Note: the lines on this graph represent the duration of disease with the left end point representing the date that the disease was first diagnosed and the right end point representing the date that the patient died. In the left graph, subjects are ordered by time of initial diagnosis. A cross-sectional study in January 2002 selected those patients who were alive at that time (indicated with vertical line). Notice that patients diagnosed before 2002 with a short survival would have less probability of being selected compared to subjects diagnosed the same period but with a longer survival. In the graph on the right, patients with the shortest survival times appear at the bottom of the graph and the patients with the longest survival times appear at the top. Notice how rarely the patients with short survival times appear among the prevalent cases.

smokers without dementia. The study was a population-based cohort of 668 people aged 75–101 years in Sweden (Wang et al. 1999). Smoking was negatively associated with prevalent Alzheimer's disease (adjusted odds ratio = 0.6, 95% confidence interval (CI) 0.4–1.1). Over 3-year follow-up (1989–1992), the hazard ratio of incident Alzheimer's disease due to smoking was 1.1 (95% CI 0.5–2.4). In addition, mortality at follow-up was greater among smokers in demented (hazard ratio = 3.4) than non-demented subjects (hazard ratio = 0.8). The authors concluded that smoking does not protect against Alzheimer's disease and that the cross-sectional association might be due to differential mortality.

When examining prevalent cases an additional problem may occur if diseased persons modify their exposure or if disease affects measures of exposure, for example, the presence of disease distorting biomarker levels. Treatment with insulin of diabetes mellitus type 1 is an example. Before insulin was available, patients had a very poor survival of less than 1 year. At that time, a cross-sectional study would simply not identify many diabetics. With insulin treatment, survival has spectacularly increased to more than 20 years. A cross-sectional study evaluating diabetes and use of insulin would therefore find an association, simply because diabetics take insulin while non-diabetics do not. This bias has also been described as a type of Neyman bias (incidence-prevalence bias) but in reality it is rather a case of reverse causation provoked by misclassification due to an erroneous evaluation of timing of exposure.

In recent years there has been an increase in the number of studies using data from large surveys such as the NHANES. Experimental data suggest that phthalates, a widespread contaminant, could produce metabolic derangements that may lead to obesity. The association between urinary phthalate metabolites and body mass was examined in a cross-sectional analysis of 2884 children 6–19 years of age who participated in the 2003–2008 NHANES. Phthalates were measured at one time point and monoesters of phthalates typically have half-lives of around 24 hours. An association of phthalates with childhood obesity was identified among non-Hispanic black children while no significant associations were identified in any other ethnic groups. Making maximum use of a resource such as the NHANES is understandable and advisable given its cost and the population sampling and these findings should lead to additional research. However, making causal inferences from this type of cross-sectional data may be complex. Reverse causation may be a problem in cross-sectional analyses since both physiological aspects and behavioural pathways, for example, restricted mobility of subjects with disease, may influence measured exposures. The London bus drivers' study in the 1950s is a classic example of potential reverse causation.

The study by Jerry Morris on the incidence and prevalence of cardiovascular disease among London bus drivers and conductors (Morris and Dale 1955) is an example of selection bias in a cross-sectional study. Bus drivers in London were shown to have very different lipid profiles, blood pressure patterns, and eventually cardiovascular disease risk compared to bus conductors. Bus drivers were less physically active on the job than conductors, but could the difference in cardiovascular disease risk be ascribed to physical activity? One potential alternative explanation was that some characteristic of the persons such as obesity, could have led to self-selection in a job that was more (bus conductors) or less

(bus drivers) active. The studies in London busmen were eventually the first to convincingly demonstrate the importance of physical activity for health.

The healthy worker effect may lead to an underestimation of an association in case-control studies that evaluate occupation and disease at a specific point in time (Checkoway et al. 2004). This happens because workers with health problems at work are more likely to change jobs than subjects without symptoms. In this case the selection is out of the job, contrary to what was a potential problem in busmen. Any cross-sectional evaluation will, therefore, not capture cases that have occurred in the past and will over-represent healthy individuals who have stayed in the job. An example of this was observed in a cross-sectional study on occupational asthma in Spain (Kogevinas et al. 1996). Subjects were asked about their current occupation and about current respiratory symptoms. The prevalence odds ratios (PORs) for asthma in subjects employed in high-risk occupations was 1.4 with 95% CI of 0.6–3.3. Subjects were also asked whether they had suffered respiratory symptoms in the past and, if yes, what type of job were they doing. The POR for employment in a high-risk occupation at the time of respiratory problems was 2.8 (95% CI 1.5–5.2) indicating that, indeed, the cross-sectional analysis failed to identify health risks due to the selective migration of subjects with respiratory symptoms out of high-risk jobs.

This type of bias is less of a problem if current exposure is a reliable surrogate for past exposure and is not a problem for non-changeable characteristics, for example, race, gender, and genetic variability. Case-control or cross-sectional studies are currently the most widely applied designs evaluating the effects of genetic susceptibility, such as the effects of SNPs (single nucleotide polymorphisms), on disease risk.

Social desirability bias has long been recognized and falls within the wider category of misclassification (Armstrong et al. 1994). Requesting information on behaviours that are regarded as sensitive by respondents may lead to refusal to participate or may lead to a tendency to over-report behaviours regarded as socially desirable (or, what is the same, under-report what is regarded as socially undesirable). This has become particularly evident in recent years in large surveys that inquire into health-related behaviours such as sexual activity and drug use.

There is extensive research showing that self-administered questionnaires lead to more valid information on socially sensitive issues compared to face-to-face interviews (Schuman and Presser 1981; Armstrong et al. 1994). In recent years the use of computers in soliciting information has considerably expanded. In addition to CAPIs (computer-assisted personal interviews) the technique of audio-computer-assisted self-interviewing (ACASI) has been proposed as an efficient method to enhance validity when evaluating behaviours that could be perceived as socially undesirable (Turner et al. 1998). In ACASI (also quoted as audio-CASI), respondents hear the questions through headphones and enter their responses directly into a computer. An experimental comparison of sexual behaviours in adolescent males using a paper-and-pencil self-administered questionnaire and ACASI identified an almost fourfold increase in the number of respondents reporting male-male sexual contact in the ACASI (5.5 per cent) as compared to 1.5 per cent in the paper-and-pencil questionnaire (Turner et al. 1998). Among the reported advantages of ACASI is that it reduces

the literacy requirements of respondents compared to other forms of self-administered questionnaires (paper and pencil or computer assisted). ACASI has been tested in multiple settings and has generally been shown to provide higher estimates of prevalence of social undesirable behaviours compared to face-to-face interviews (Ghanem et al. 2005). Results are less consistent when comparing ACASI with self-administered questionnaires (Morrison-Beedy et al. 2006). Different computer-assisted methods (audio or text) may have little impact on reported socially undesirable behaviours and the choice of one method over another should be based on an evaluation of wider considerations on the study settings.

Analysis of cross-sectional studies

Prevalence is the ratio of the number of cases of a disease in a population at a particular time, to the size of the population at that time.

$$\text{Prevalence} = \frac{\text{number of existing cases of disease}}{\text{total population at a point in time}}$$

Point prevalence is estimated at one point in time, while period prevalence denotes the number of cases in a time interval (e.g. 1 year).

For example, in a given state in June 2007, there were 14,000 women with a diagnosis of breast cancer. The total female population in June 2007 was 1,558,000 women. The prevalence of breast cancer in this population on this specific date is 14,000/1,558,000, which equals 0.009 (or 0.9 per cent). This means that nearly 1 per cent of the women in June 2007 had breast cancer, a figure that corresponds to the actual prevalence of this disease in several industrialized countries. This estimate does not show how many new cases of breast cancer occur each year or when the 14,000 women had their disease diagnosed. In these types of estimates it is usually assumed that none of the persons diagnosed with a chronic disease is entirely cured, although such calculations could be incorporated into the estimation of prevalence.

Prevalence is, strictly speaking, a proportion although it is sometimes indicated, erroneously, as a rate. However, the term 'prevalence rate' should be regarded theoretically as an impossible concept (Elandt-Johnson 1975).

Prevalence reflects determinants of incidence as well as survival (duration of a disease). The prevalence of bladder cancer in the United States in January 2004 (377,523 persons alive with a history of bladder cancer) was higher than that of lung cancer (174,880 persons), even though the incidence of lung cancer (81.2 per 100,000) was clearly higher than that of bladder cancer (37.3/100,000). This is a reflection of the much better prognosis of bladder cancer (5-year relative survival rate of 79.5 per cent) compared to 15 per cent for lung cancer (National Cancer Institute n.d.).

In its most simple expression prevalence odds are equal to incidence rate times the duration of the disease:

$$\frac{P}{1-P} = I \times D$$

where P is prevalence, I is incidence, and D is duration (survival). This, however, is only true under stable conditions, that is,

unchanging rates and population structure that are unlikely in most occasions in true populations. If two populations are compared, say 1 indicating the exposed and 0 the non-exposed, then the POR can be calculated as:

$$\text{POR} = \frac{P_1 / (1 - P_1) I_1 D_1}{P_0 / (1 - P_0) I_0 D_0}$$

If the duration of the disease is expected to be equal in the exposed and unexposed, then the POR is equal to the incidence rate ratio (under steady conditions in the population). Under the same conditions, the ratio of prevalences (as compared to the ratio of prevalence odds) will only estimate the incidence rate ratio if the prevalence of the disease is low. In that occasion, $1 - P$ would be roughly equal to 1.

There has been some controversy whether cross-sectional studies should be calculating POR or prevalence ratios (Thompson et al. 1998; Pearce 2004). The choice of one or the other depends essentially on the purposes of the research, with the POR having advantages compared to the prevalence ratio if aetiological research is conducted. However, the prevalence ratio or probably the absolute difference in prevalences may be preferred if two populations are compared regarding the prevalence of disease.

Statistical analysis in cross-sectional studies is frequently limited to descriptive statistics through the use of standard statistical measures for proportions or a comparison of distributions (e.g. blood pressure) between an exposed and an unexposed group. Standard statistical tests comparing means of a distribution such as Student's *t*-test can be used. For the evaluation of multiple variables, standard techniques such as multiple linear regression can be used. For dichotomous outcomes, the POR is the most common effect measure estimated in cross-sectional studies comparing groups, with the application of logistic regression or equivalent techniques. A wide range of other analytical regression techniques is readily available for the modelling of prevalence ratios (Thompson et al. 1998; Barros and Hirakata 2003). The selection of the effect measure, that is, POR versus the prevalence ratio as the preferred effect measure, should, therefore, not depend on the availability of statistical tools (Pearce 2004), but rather on the objectives of the research.

Summary

Cross-sectional studies are among the most applied designs. The principal characteristic of cross-sectional studies is that they provide information on the prevalence of disease. In many cross-sectional studies information on past exposures is not collected but this should not be regarded as a characteristic defining these studies. On many occasions, cross-sectional studies tend to follow a hybrid design, an analysis incorporating aspects of cohort and of case-control studies. Repeated cross-sectional studies (panel studies) offer the possibility of assessing short-term and long-term physiological changes. Cross-sectional studies are extensively used to evaluate the prevalence of disease. Large cross-sectional studies are conducted in several countries to provide background information on health-related variables including health services use. In recent years these surveys have

also incorporated the collection of biospecimens. In aetiological research, cross-sectional studies are suitable epidemiological means for studying non-fatal diseases and effects on physiological variables that do not have a clear time of onset. However, the design of cross-sectional studies makes them less appropriate than other study designs for investigating causal associations. Among the major limitations of cross-sectional studies are the inclusion of prevalent rather than incident cases and the frequent lack of information on past exposures and on the time sequence of events. The representativeness of the sample is crucial when evaluating prevalence of a disease and several policies have been developed to increase participation in studies, reduce non-response, and improve the quality of the recorded information.

Principles of outbreak investigation

Kumnuan Ungchusak and Sapon Iamsirithaworn

Introduction to principles of outbreak investigation

Knowledge of medicine and diseases has increased enormously over the last few decades. With the advance of knowledge, public health services in many countries can implement effective prevention programmes, and are able to protect people from many avoidable illnesses and death. However, people around the world still suffer and die from various known and unknown outbreaks of disease. Some outbreaks are old diseases that have re-emerged, some are newly identified or emerging, and some have been deliberately started. Outbreaks can occur anywhere, from a very remote area where no health facility exists to nosocomial outbreaks in a very sophisticated hospital where hundreds of health personnel are employed. Moreover, outbreaks may even spread across borders thereby threatening international health security. It is a challenge for governments and public health professionals of all countries to detect and control these outbreaks as early as possible. Outbreak investigations provide the opportunity to discover new aetiological agents, to understand factors that promote the spread of the diseases, and to identify the weaknesses of existing prevention and health programmes. For these reasons, all public health professionals should have the ability to detect, conduct, or play essential roles in supporting outbreak investigations.

This chapter provides a definition and describes the objectives of outbreak investigation, the methods for planning and conducting an investigation, and what needs to be done after the investigation has been completed. For simplicity, mainly examples of communicable disease investigations are discussed; however, the concepts and principles can also be applied to non-communicable diseases and injuries.

What is an outbreak?

The terms *outbreak* and *epidemic* can be used interchangeably. However, most people understand the term *outbreak*, which conveys a greater sense of urgency. Some epidemiologists prefer to use the term *epidemic* only in a situation that covers a very wide geographical area and involves large populations. For example, it is possible to use the term 'outbreak of HIV' to describe a sharply increasing HIV prevalence rate among commercial sex workers in a city where the normal rate was low in the previous year. However, the term *HIV epidemic* can be used when an abnormally

high HIV prevalence is found among sex workers in many cities of the country.

In general, infectious diseases can be newly emerging and once the disease is able to sustain its transmission in the population of a geographical area we call it an endemic disease. Outbreak is used for a new emerging disease or situation when an endemic disease or health events occur at a greater frequency than normally expected within a specified period and place. There is often a misunderstanding that only communicable diseases can cause outbreaks. Non-communicable outbreaks such as mass sociogenic illnesses are sometimes reported as acute outbreaks of unexplained illness, especially in school settings (Centers for Disease Control and Prevention 1990, 1996). Another example of an event that can be called an outbreak and needs investigation is mass casualty. Following a fire in a pub on New Year's Eve 2009 in Thailand, an unprecedented number of 67 deaths and 153 hospitalizations resulted (Jongcherdchootrakul et al. 2010).

Because the criteria for judging an outbreak can be very subjective, it is useful to define the term in a more measurable manner. The criteria for judging that an outbreak has occurred can be one of the following:

1. The occurrence of a greater number of cases or events than normally occurs in the same place and during the same period as in past years. An example is detection of influenza outbreaks in the United States. The surveillance data from the 122 sentinel cities provides the seasonal baseline mortality attributed to influenza and pneumonia on a weekly basis, and an influenza outbreak is signalled by a rise of the mortality rates above the epidemic threshold. Another example is the epidemic of Kaposi's sarcoma, a manifestation of AIDS, confirmed in New York when almost 30 cases were reported in 1981, whereas only two or three cases had been reported in previous years (Biggar et al. 1988).
2. A cluster of cases of the same disease occurs that can be linked to the same exposure. The term *cluster* means aggregations of relatively uncommon events or diseases in space and/or time in amounts that are believed or perceived to be greater than could be expected by chance (Porta 2008). For example, in Denmark during August 2007, the Danish clinical notification system identified many cases of *Shigella sonnei* among employees of two companies. The patients had eaten in their workplace canteen, which were served by the same catering company (Lewis et al. 2009).

3. A single case of disease that has never occurred before or might have a significant implication for public health policy and practice can be judged as an outbreak that merits investigation. The first documented case of avian flu (H5N1) in the Hong Kong Special Administrative Region in a 3-year-old boy in May 1997 alerted the local authorities and scientists around the world to start a full-scale investigation (Lee et al. 1999).

How can an outbreak be detected?

Public health professionals need to maintain monitoring or surveillance of the disease situation in their local area or country, and also at the international level. It is possible to identify an outbreak by monitoring many sources of information, which will help to detect the abnormal occurrence of disease. Some useful sources are listed as follows.

Health personnel

Doctors and nurses in hospitals have a good opportunity to observe an abnormal increase in the number of patients with a particular disease or syndrome. A cluster of food poisoning in a northern province of Thailand was reported to an epidemiologist during a business telephone conversation with his colleague. The epidemiologist started an investigation and identified the first confirmed outbreak of *Clostridium botulinum* food poisoning associated with home-canned bamboo shoots in the country (Centers for Disease Control and Prevention 1999a). Without this personal contact, the outbreak would not have been investigated. Thus, public health authorities should maintain a cordial relationship with doctors and hospital staff, both in the governmental and private sectors. Conversely, doctors should report all suspected outbreaks to local public health authorities.

Laboratories

Every laboratory or network can serve as an excellent source of outbreak notification. The avian flu outbreak in the Hong Kong Special Administrative Region was first discovered by the Influenza Surveillance Network, which reported an abnormal influenza type A (H5N1) (Lee et al. 1999). Without the necessary laboratory capacity, avian flu might have been overlooked and not have triggered a field investigation. A public health professional should communicate regularly with laboratory technicians and vice versa. Laboratory scientists can prevent further spread if they report abnormal findings to public health authorities regularly and without delay.

Official disease notification systems

Most countries have official systems for notification of cases and deaths of epidemic-prone diseases in hospitals. The system was designed to detect outbreaks by comparing cases occurring in the current week or month with the average number of cases in the same area during the same period in past years.

For some diseases such as HIV/AIDS, a sentinel surveillance system was designed to monitor and detect abnormal trends in particular sentinel populations and sites. The first HIV sentinel serosurveillance in Thailand, which started in June 1989, detected HIV prevalence of 44 per cent among commercial sex workers in a popular northern tourist province. This finding was very alarming, and prompted a field investigation to confirm the high

prevalence and to look for risk factors of HIV infection among sex workers (Siraprapasiri et al. 1991). The investigation confirmed the outbreak and revealed low levels of condom use, which led to a recommendation for promoting condom use in this high-risk population.

One of the most important functions that epidemiologists and public health professionals perform is regular analyses of reported disease data. Unfortunately, this task has been neglected, and the usefulness of disease reporting systems has been downgraded and often serves only as vital statistics reports. If this neglect of the reporting system can be overcome, the public health system will regain this powerful tool to detect and control outbreaks.

Newspapers and media

Public health professionals learn of outbreaks from the media more often than from the official surveillance system. Newspapers receive outbreak news directly from their journalists or people in the community, and are able to report them immediately. The Programme for Monitoring Emerging Diseases (ProMED) was the prototype for a communication system that monitors emerging infectious diseases globally, an initiative of the Federation of American Scientists co-sponsored by the World Health Organization (WHO), which obtains much of its outbreak news from the local or international media. Although timeliness is the strength of the media, the validity of the information is often of concern, so media reports require verification.

Village health volunteers

In rural areas where there are no health facilities and communication is limited, village leaders or village health volunteers can often help to recognize an abnormal increase in the numbers of some clinical diseases, such as diarrhoea, dysentery, measles, fever, deaths from unknown aetiology, etc. For example, between 2004 and 2005 there was a nationwide outbreak of avian influenza (H5N1) in poultry. The Thai Ministry of Public Health asked the village health volunteers to report any abnormal deaths of poultry to local health officers and the animal health authorities. With these notifications from villagers and a policy to provide compensation to households that lose chickens through culling of the suspected infected flock, Thailand was able to control the highly pathogenic avian influenza outbreak in chickens that then resulted in only 25 human cases.

Purposes of outbreak investigation

An outbreak investigation can have many purposes, but the critical ones are as follows.

Controlling the current outbreak

This should be the primary ultimate goal. If the investigation can start early, the findings can guide implementation of appropriate control measures to stop further spread. The avian influenza (H5N1) outbreak investigation found a link between infection and illness in chickens and humans. The same virus was found in both. There were a total of 18 cases and six deaths before the Hong Kong Special Administrative Region decided to kill all of the 1.5 million chickens in the islands within 3 days to end the outbreak (Lee et al. 1999). There have been no human cases in Hong Kong since then. However, the outbreaks of avian influenza (H5N1) in poultry

Sequence of events in outbreak detection and confirmation: scenario 1

Sequence of events in outbreak detection and confirmation: scenario 2

Fig. 5.4.1 The impact of early detection of and response to outbreak in reducing a disease burden.

Reproduced with permission from Connolly M.A (ed.), *Communicable Disease Control in Emergencies: A Field Manual*, World Health Organization, Geneva, Switzerland, Copyright © World Health Organization 2005, http://www.who.int/hac/techguidance/pht/communicable_diseases/field_manual/en/.

have re-emerged in several countries in Asia and other continents, with increasing numbers of human cases since late 2003. Up to 17 December 2012, there were 610 human cases of H5N1, including 360 deaths reported in 15 countries. To achieve the goal of controlling the current outbreak, it is necessary to eliminate the delay in detecting the outbreak, to start an investigation as soon as possible, and to immediately implement appropriate preventive and control measures indicated by the investigation results. With early cases detection and timely report to an outbreak response team, an opportunity of reducing a disease burden is potentially greater (Fig. 5.4.1).

Prevention of future outbreaks

Not all investigations start at the beginning or before the peak of the outbreak. The findings or lessons learned from the investigation may be too late to help fully control the current outbreak, but they can still contribute to prevention of future outbreaks. Through sound investigations, the weaknesses of the prevention programmes and/or necessary measures can be identified. If recommendations are taken seriously, the chance of recurrence of the

same outbreak or other diseases that share common risk factors can be reduced. There was a thorough investigation of a reported case of a neurological syndrome after eating a common local dish of fish-porridge in Bangkok during October 2002. The investigation revealed that the meat was from puffer fish, which is widely used as a substitute because it is less expensive and easy to obtain from large markets. The result of the investigation was presented to the authorities of the Thai Food and Drug Administration. A new regulation to prohibit selling of puffer fish was enacted to minimize a risk of tetrodotoxin poisoning from puffer fish consumption in the country (Samitsuwan et al. 2005).

Research to provide knowledge of the disease

Information about new diseases and their natural history, clinical spectrum, incubation periods, etc. can often be best learned during an outbreak investigation. Outbreak investigation can help ascertain new information, for example, modes of transmission, population at risk, and so on, and so provide essential information which can significantly contribute to the medical/public health literature. The outbreak of encephalitis in Malaysia, which continued until the end of April 1999 and resulted in 257 cases and 100 deaths, prompted an international outbreak investigation, resulting in the discovery of a new virus, Nipah (Centers for Disease Control and Prevention 1999b, 1999c). The mode of transmission was close contact with infected pigs through blood and secretions.

Evaluation of the effectiveness of prevention programmes

Investigation of an outbreak of disease, which is the target of a public health programme, may reveal weaknesses in that programme. Investigation of an outbreak of vaccine-preventable diseases often identifies populations that have not received the vaccine. For example, investigation of a measles outbreak that occurred in 1993 in Espindola, a rural community in the Peruvian Andes, revealed that more than a quarter of the 553 residents were affected, and that more than 3 per cent of those who contracted measles had died. One year before the outbreak, a national measles campaign targeting children younger than 15 years had been conducted. Although national data reported the coverage to be 78 per cent, the investigation revealed that only 4 per cent of the children in Espindola had actually been vaccinated (Sniadack et al. 1999).

Evaluation of the effectiveness of the existing surveillance system

Some aspects of the surveillance system can be evaluated during an outbreak, such as the timeliness, validity, sensitivity, appropriateness of case definitions, and utilization of the surveillance information.

Training of health professionals

The Epidemic Intelligence Service of the US Centers for Disease Control and Prevention (CDC) and over 50 field epidemiology training programmes around the world use real outbreaks as an opportunity for training health professionals, as well as to provide emergency services by investigating the causes and determinants of outbreaks. Recommendations and action taken by these applied epidemiology programmes resulted in a limited scale of outbreaks and improved the health of the public.

Responding to public, political, and legal concerns

In many situations, an investigation must be conducted because the media has publicized the complaints of people to politicians, or even rumours. The main objective for this kind of investigation is to verify the outbreak and diagnosis. If it is groundless, the investigator can supply the media with new information that can end the rumours. Conversely, if it is a true outbreak, investigators must decide on what steps need to be taken.

In general, for a real outbreak, many objectives can be achieved fully or at least partially. However, the ultimate goal is to control the current outbreak and to prevent future ones. It is unethical for investigators to compromise this ultimate goal with other goals such as training or non-essential research that does not directly contribute to control activities.

Components of an investigation team

In this chapter, the term *investigators* will represent people who are directly involved in planning and conducting outbreak investigations from start to finish. In principle, local health professionals at the district or provincial level should assume the role of investigators and start work as soon as possible. For complicated or difficult field investigations, additional disciplines or international experts can provide assistance. It is best to form an investigation team with a team leader in charge of the operation. A good investigation team should include the following:

1. A field epidemiologist who is technically competent to conduct field investigations systematically. The field epidemiologist usually serves as one of the primary investigators, and should be involved in all the investigative steps.
2. Disease control specialists who are experienced in implementing basic disease control measures such as food and environmental sanitation, vector control, and vaccination. If available, an educator who can provide essential knowledge to villagers in clear terms is also very useful for disease control implementation.
3. Laboratory technicians who are able to provide basic and advanced laboratory support to the investigation team. They might not need to travel to the field and collect the specimens themselves, except when a special collection procedure is required.
4. Specialists in particular areas (e.g. veterinary medicine) would be very helpful for an outbreak investigation of zoonotic diseases. An entomologist is a key team member for an outbreak investigation of vector-borne diseases. A social scientist with expertise in qualitative methods can help identify risk behaviours among affected populations and assess the acceptability of the recommended interventions.
5. Public health administrators who are good at providing logistic support, mobilizing resources, and providing administrative expertise for the team.
6. In certain situations, when the outbreak has caused panic or has gained the intense attention of the public, the investigation team should recruit or appoint a person to be in charge of public relations and press releases. This person should appropriately reassure and not unduly alarm the public.

In practice, all of these team members are not always available at the subdistrict or district level, due to limited human resources. Public health professionals and field epidemiologists need to have basic knowledge of all these relevant disciplines and be able to assume these tasks if needed. In the event of a technical problem or the need for consultation from the field, telecommunication equipment should be provided to field investigators.

Due to the sudden nature of a field investigation, it is best to establish in advance a list of people who will be on call and are ready to join an investigation team once an outbreak has occurred. The Thai Ministry of Public Health established 1030 Surveillance and Rapid Respond Teams to serve as investigation and control teams at all districts nationwide when the avian influenza outbreak occurred in early 2004. Public health officers received practical epidemiology training, and subsequently became frontline armies tracking outbreaks in their local area.

Issues to be considered before implementing an investigation

The team leader should consider all of the following issues before initiating a field investigation.

Assessing the existence of the outbreak

No matter how outbreak news is obtained, an investigator should confirm the validity of the information. The best way is to have direct communication with the responsible local health authority or field staff. It is not unusual for the information to be groundless. Sometimes, the outbreak has in fact occurred, but the media incorrectly quoted the name of the location. The investigator should carefully check with all other possible local health authorities so as not to overlook the outbreak.

Gathering available basic information

If the local health authority or field staff confirms the existence of the outbreak, the investigator should ask for additional information related to the situation and control measures being implemented. It is not necessary to gather all of the following listed information before leaving for the field, but having it will help investigators to plan an effective investigation.

Information related to the disease situation

1. What are the main symptoms and signs of the patients?
2. By whom and how was the diagnosis made; for example, using only clinical or also laboratory evidence?
3. How many patients were seen and how many died?
4. What was the average age of the patients and were there any differences in gender distribution?
5. Where did the patients come from? Are they clustered or scattered?
6. When was the increased number first observed and what is the trend at the moment?

Information related to control and response activities

1. What has already been done in terms of the field investigation and implementation of control activities?

2. Are there any serious constraints that compromise the field investigation and/or implementing control measures?
3. Who are the key people responsible for the investigation and control activities?

Ensuring that clinical specimens and suspected materials are collected in a timely and appropriate manner

It is absolutely critical to contact the doctors who saw the cases and made the diagnosis to obtain relevant clinical specimens such as serum and blood for future laboratory tests. The items to which the cases were exposed, such as food and water, should be collected immediately before anything is unintentionally destroyed. The investigator should contact the local and reference laboratories so that the necessary supplies and equipment can be obtained immediately.

Obtaining permission and adequate support from local and national authorities

The investigation team should ask the permission of the local health authorities, which will create a sense of shared responsibility and partnership. Usually local authorities are pleased to receive assistance. In a few situations, the local authority might be unhappy about having outsiders conduct the field investigation because of the sensitive nature of the problem. The investigator needs to convince local authorities that a thorough and sound investigation will incur more benefits than harm. The investigator should also request field support from the key authorities, such as field staff who will facilitate the fieldwork and provide transportation, medication, etc. In some situations, if the outbreak is possibly of international concern spelled out by the 2005 International Health Regulations, the principal investigator should inform national authorities so they are aware and can plan further necessary steps to report to WHO and deal with the media and international communities.

Planning the field operation

The investigator needs to have a short meeting with team members to summarize the situation, set up the objectives of the investigations, divide responsibility among team members, and check the readiness of laboratory and logistical support.

It is also important to plan the duration of the field investigation. The investigation team should stay in the field until all investigation processes such as data collection, analysis, interpretation, and the executive summary have been completed. Leaving the field without accomplishing all these objectives could delay the implementation of control measures. Most outbreak investigations should plan to obtain preliminary results and recommendations within a week of the start of the investigation to ensure that the findings will be timely enough for control of the current outbreak. Additional studies and subsequent investigations can be conducted later.

The investigation team should not spend too much time preparing a perfect plan, because of the urgency of the outbreak; rather, they should obtain what is most necessary and start the investigation as soon as possible.

Steps of outbreak investigation

An outbreak investigation is an observational study by nature, because the events have already occurred. Every outbreak

investigation needs to start with a good descriptive study, followed by analytical studies whenever possible and necessary. Conclusions about the causes, sources, mechanisms, and determinants of the outbreak need to be drawn, based on sound epidemiological, clinical, laboratory, and environmental evidence.

A descriptive study can help to identify the risk population(s) and risk area(s) so that immediate interventions can be directed to those who need them the most. A good descriptive study can also generate hypotheses about how the outbreak has spread and what factors contributed to the abnormal occurrence of the disease. In theory, hypotheses derived from a descriptive study should be confirmed by further analytical study; in reality, this is not always possible, due to many constraints.

It is preferable to translate the methodology for outbreak investigation into steps of action. Gregg (1996) has divided the outbreak investigation process into ten steps; with a slight modification, this ten-step investigation process has been summarized in Box 5.4.1. Steps 1–4 use descriptive epidemiology to generate basic facts and hypotheses, steps 5–7 are processes to test the hypotheses and draw conclusions, and steps 8–10 emphasize the importance of communication of the results and follow-up of the recommendations.

This outline does not imply a strict course of action. In real outbreak investigations, many steps may be undertaken concurrently, depending on the situation.

Step 1: confirm the existence of an outbreak

The main question is: 'Is this a true outbreak?' Applying the definition of an outbreak outlined in this chapter, the investigator

Box 5.4.1 Ten steps to take in an outbreak investigation

1. Confirm the existence of the outbreak.
2. Verify the diagnosis and determine the aetiology of the disease.
3. Develop a case definition, start case finding, and collect information on cases.
4. Describe persons, places, and times, and generate hypotheses.
5. Test the hypotheses using an analytic study.
6. Carry out necessary environmental or other studies to supplement the epidemiological study.
7. Draw conclusions to explain the causes or the determinants of the outbreak, based on clinical, laboratory, epidemiological, and environmental studies.
8. Report and recommend appropriate control measures to concerned authorities at the local, national, and if appropriate, international levels.
9. Communicate the findings to educate other public health professionals and the general public.
10. Follow up the recommendations to ensure implementation of control measures.

Source: data from Gregg M.B. (ed.), *Conducting a field investigation*, p. 44–59, in *Field Epidemiology*, Oxford University Press, New York, USA, Copyright © Oxford University Press, Inc. 1996.

should be able to establish or refute the existence of the outbreak. Investigators should review the number of cases with the local health officers or hospital staff and compare it with the number found during the same period recorded in past years.

For example, the outbreak of trichinosis in North Rhine-Westphalia, Germany, was confirmed because there were 52 cases in a 3-month period between November 1998 and January 1999, compared with no more than ten cases annually during the same time period in the past 10 years (Centers for Disease Control and Prevention 1999d).

Step 2: verify the diagnosis and aetiology of the disease

If the number of cases fits the case criteria for the outbreak, the next related questions are:

1. What is the correct diagnosis and aetiology of the disease?
2. What can be done immediately to prevent new cases from occurring?

Knowing the exact diagnosis and aetiology of the disease will help to establish appropriate preventive measures immediately. This will protect susceptible people and allow the team to start educating villagers to avoid the risk factors. For example, many adults in a remote village were ill with fever, muscle and joint pain, rashes, etc. If the diagnosis and aetiology of the disease is unknown, the local public health officials will find it very difficult to educate the public or implement effective preventive programmes. Until the serology of some patients showed sharply rising immunoglobulin M (IgM) antibodies to dengue virus, control measures to destroy the larvae of the *Aedes* mosquito, the vector of dengue which breeds in water containers, could not be started.

In many situations, an unknown or unclear diagnosis can cause panic due to rumours. This was demonstrated by an outbreak of pneumonic plague in Surat, India in 1994, and of encephalitis in Malaysia in 1999, which resulted in severe panic among local people and foreign tourists. Thus, it is very important to obtain the exact diagnosis as rapidly as possible.

Investigators should have basic knowledge of the clinical diagnosis and how to confirm the aetiology of suspected disease by using well-established laboratory techniques. It is recommended that investigators visit and talk with some patients, review and visualize the signs and symptoms, and hold discussions with the attending doctors. The information from this step will help to develop a case definition to facilitate active case-finding. The information on aetiology will also help to interpret the findings from the later descriptive study and establish a causal association.

The investigators should also visit the laboratory facilities and ask for either positive or negative results of the testing of specimens. It is not necessary for all cases to be laboratory confirmed, but at least some of the apparent clinical cases or deaths should be confirmed. Once there are laboratory-confirmed cases, the investigator will find it more reasonable to assume that other cases with the same clinical manifestations in the same period and location are the same disease.

It is unfortunate that specimens from patients are often thrown away when the primary results (either positive or negative) are obtained. The investigators should plan with the doctors and laboratory scientists to perform further investigations on the specific strain, and to establish drug sensitivities, genetic markers, etc.

Many new laboratory technologies, such as serological testing, culture and isolation, and molecular techniques, are very powerful for diagnosing and tracking the connections between cases, even in different geographical areas. For example, outbreaks of *Shigella sonnei* infections in Denmark and Australia were detected during the same week in August 2007, and 215 laboratory-confirmed cases were reported in Denmark, with an additional 12 cases in Australia. Antibiotic resistance and pulsed field gel electrophoresis in isolates identified in those two outbreaks were indistinguishable. A hypothesis that the patients were exposed to the same implicated food item from the same original source was soon proved (Lewis et al. 2009).

Step 3: develop an appropriate case definition, start case finding, and collect information on cases

At this stage, the investigator needs to answer at least three questions:

1. Who should be counted as a case?
2. Are there more undetected cases in the hospitals and in the community?
3. What are the characteristics of cases?

To answer these three questions, the investigators must follow three steps.

Develop an appropriate case definition

It is important that the investigator develop a case definition, which will be applied consistently during the investigation. The definition should be sensitive or adequate at the beginning, in order to capture actual cases. A good case definition for investigative purposes should be specific to time and location. The case definition should not include any specific suspected exposure that the investigator plans to verify. This would create selection bias when the investigator generates the hypothesis or tests the hypothesis in the subsequent steps. Using the information obtained from the previous steps, the investigator can divide the case definition into different levels.

For example, in September 2012, when two patients with a novel coronavirus from Saudi Arabia and Qatar were found, WHO requested member states to start surveillance of the disease by using the interim case definitions as shown in Box 5.4.2.

Active case finding

In places where there is good surveillance, cases from all hospitals can be reported to the epidemiology unit at the district or provincial level. Investigators can apply the case definition and count the number of cases, and review data that are collected on the reporting form. If enough cases and basic information on cases have already been gathered, investigators can start descriptive epidemiology.

Conversely, if only a few cases have been seen at the health facility, the investigators should plan to search for more cases in the community. The investigator must start a process called *active case finding*. The objective of active case finding is to have enough cases to analyse. At the same time, this case finding will give a better picture of the magnitude of the outbreak. Investigators must frequently visit many hospitals in the outbreak area and review medical records themselves. Sometimes, they must search

Box 5.4.2 WHO interim case definitions for a novel coronavirus**1. Patients to be investigated (referred to as 'patient under investigation'):**

- ◆ A person with an acute respiratory infection, which may include fever ($\geq 38^{\circ}\text{C}$, 100.4°F) and cough; *and*
- ◆ Suspicion of pulmonary parenchymal disease (e.g. pneumonia or acute respiratory distress syndrome (ARDS)), based on clinical or radiological evidence of consolidation; *and*
- ◆ Travel to or residence in an area where infection with novel coronavirus has recently been reported or where transmission could have occurred (see updated area in WHO website) *and*
- ◆ Not already explained by any other infection or aetiology, including all clinically indicated tests for community-acquired pneumonia according to local management guidelines.

2. Probable case

- ◆ A person fitting the definition given in (1) of a 'patient under investigation' with clinical, radiological, or histopathological evidence of pulmonary parenchyma disease (e.g. pneumonia or ARDS) but no possibility of laboratory confirmation either because the patient or samples are not available or there is no testing available for other respiratory infections, *and*
- ◆ Close contact with a laboratory confirmed case, *and*
- ◆ Not already explained by any other infection or aetiology, including all clinically indicated tests for community-acquired pneumonia according to local management guidelines.

3. Confirmed case

A person with laboratory confirmation of infection with the novel coronavirus.

for cases in each village by interviewing house to house, which is the true nature of outbreak field investigations and the way people learn epidemiology. This active case finding in the community also provides two more benefits:

1. Control measures can be implemented if the aetiology of the disease is known and treatable. During an investigation, using active case searching in a village that reported seven deaths from malaria in Kachin state in the Union of Myanmar, the investigator found 94 probable cases and 53 microscopically confirmed malaria infections. All of the probable and confirmed cases

found by this active process were treated. Without this measure, there might have been more deaths later on (Dr Myint Win, personal communication, 1999).

2. Rapid environmental assessment can be started during the visit to the affected families or villages. From the direct interview with the cases, the investigators can develop hypotheses and implement necessary interventions immediately, such as sanitation improvement among food handlers and treatment of water to prevent a waterborne outbreak.

In situations in which the outbreak is not localized but widespread, the investigator might need to use the media to alert the public about the outbreak. People can then avoid suspected exposures and see a healthcare provider if they have developed symptoms compatible with the case definition.

Collecting information on cases

For each case, the investigator should collect at least four types of information:

1. Identifying information: name, hospital number, contact person, and address of contact. This additional information will help to avoid duplication of enumerated cases. The investigator can also maintain communication with these cases when more information is needed.
2. Demographic information: age, gender, occupation, religion, ethnicity, area of residence, place of employment, etc. This important information may help to determine the characteristics and distribution of cases.
3. Clinical information: symptoms and signs, date of onset, duration of illness, and results of diagnostic procedures. These data will help to confirm a true case, provide the pattern of clinical manifestations, and also the distribution of cases by time.
4. Suspected risk factors: investigators can ask for a history of exposure to factors before the disease developed. The timing of interest is usually one incubation period if the aetiology is known or suspected. Questions about contact with other patients who have similar clinical symptoms are also very helpful. If the diagnosis is not known, the investigator should collect this information in a qualitative manner.

The investigator should develop a questionnaire as a tool to collect the relevant information from the hospitals or during active case searching in the community. In practice, some of the information will not be available or not of good quality. The investigators should validate all data in doubt.

Step 4: describe the outbreak in person, place, and time, and hypotheses formation

In this step, investigators need to answer the following questions:

1. What are the main clinical features?
2. What population(s) is at risk?
3. What are the risk factors?
4. What are the most likely explanations of how the outbreak began?

A simple approach is to analyse clinical information from each case and see the distribution of cases in terms of person, place,

and time. The analysis should be done using rates rather than absolute numbers; the investigator needs to obtain the denominators from an available source or to estimate them. Using rates, the investigator can compare and determine the populations and areas of highest risk. With the advent of computers, many software programs are available to analyse these data. A popular one is EpiInfo™, which is public domain software from the US CDC that is designed specifically for field investigations. In the absence of a computer, investigators can still analyse data manually. Individual questionnaires can be compiled into a line listing, which includes important variables of all cases. With this line listing, simple counts can be made. In this way, investigators will gain knowledge about populations and areas of risk. Resource and control measures can then be directed to the risk populations and risk areas. Enumeration will also produce information for hypothesis formation to explain how and why the outbreak occurred.

Clinical manifestations of cases

Signs and symptoms of cases can be analysed in percentages and presented in a summary table. In an outbreak of unknown aetiology, clinical information will help to establish the diagnosis. For an outbreak in which the aetiology is already known, the investigators still need to compare the clinical information found in the investigation with previous knowledge. Any discrepancy between the investigation and previous knowledge such as the attack rate, mortality rate, severity, and so on should be carefully examined, because this might indicate that a new strain or different specific host response is occurring. The high mortality rate of approximately 40 per cent in the Nipah encephalitis outbreak in Malaysia 1999 (Centers for Disease Control and Prevention 1999c) indicated that this outbreak might not be due to the usual endemic encephalitis.

Populations at risk

Investigators should analyse the characteristics of cases by gender, age, occupation, ethnicity, and so on. Initially this can be carried out by examining the proportion of all cases, but the specific attack rate by age and gender will be more useful for comparisons and hypothesis formation. The rates will provide useful indicators of the possible aetiology of the outbreak. In the Ebola haemorrhagic fever outbreak in Zaire in 1976, all ages and both genders were affected, but females slightly predominated. Age- and gender-specific attack rates indicated that adult females had the highest attack rate. This finding suggested that parenteral injection with unsterilized syringes and needles given during antenatal care in the local hospital was the means of transmission (World Health Organization 1978).

The outbreak of Nipah encephalitis in Malaysia in early 1999 was initially thought to be due to Japanese encephalitis alone. However, after careful analysis of the descriptive information, it was clear that the cases were mainly male, adult, involved in pig farming, and of Chinese ethnicity. This descriptive information did not fit the pattern for Japanese encephalitis, which mainly affects children of both genders, with no preference for a particular ethnicity. The investigator then began to suspect other organisms and to hypothesize that pig farming increased the risk of becoming ill.

Primary, index, and outlier cases

In infectious diseases, the first case on the epidemic curve is called the primary case. The primary case is important, because of the possibility that he/she brought the disease into the community either from the local area or from other locales. In investigations, sometimes the first case that draws the attention of the investigator is not the primary case. We call this the 'index case'. Index cases may be detected at the hospital or during the active case finding. The investigator may find the primary case among those who were sick in the community but did not seek medical care. Cases that appear at the very beginning or at the end of the epidemic who are markedly different from the rest of cases should also be given careful attention. These cases are called *outlier cases*, and can provide important information about the source and the way in which the disease is spread. A tourist who happened to be only a short time in the village during the outbreak and get sick is an example of an outlier.

Typically, the very first and very last cases in the epidemic curve should be critically appraised. The first case may not be the true index case because of misdiagnosis, a case unrelated to the epidemic, etc. The late cases may be due to misdiagnosis, a case unrelated to the epidemic, or a secondary case that had a different exposure than the majority of the cases in the epidemic.

During the outbreak of severe acute respiratory syndrome (SARS) in February 2003, the index case was identified as a 65-year-old medical doctor from Guangdong, mainland China, who stayed on the 9th floor of a hotel in Hong Kong (Fig. 5.4.2). He had treated patients with atypical pneumonia prior to his departure, and he was symptomatic upon arrival in Hong Kong. He infected over a dozen guests and international visitors. During the outbreak investigation, the investigators tried to identify contacts of this index case to prevent further transmission. A history and information of this index case obtained by the investigation team traced these cases back to previous atypical pneumonia outbreaks or undiagnosed SARS since late 2002 (World Health Organization Regional Office for the Western Pacific, 2006).

Location

Investigators can calculate attack rates of cases in different locations. These can be places of residence, places of employment, sites of exposure, etc. Locations with high attack rates often indicate the sources of infection or contamination. A spot map showing the locations of cases can give a very good idea of the source, as demonstrated by Snow in his classical investigation of a cholera outbreak in the Golden Square area of London between August and September 1854 (Frost 1936). In that investigation, Snow found most cases clustered around the Broad Street pump. From this information, Snow deduced that the Broad Street pump was probably the primary source of the outbreak.

If cases are scattered in many locations, investigators should explore the secular pattern of the cases over time, which will indicate whether the outbreak started in one area and spread to other areas, or whether people living in different places had a common exposure. The SARS outbreak is a good example of when cases are distributed worldwide originally from a single source of infection.

Time

The objective is to show the occurrence of cases over time and look for a pattern of occurrence. In general, there are two major types of outbreaks: a common source and a propagated source. The way to differentiate between these two patterns of outbreak is to draw an epidemic curve that shows the number of cases (on the y -axis) over time of onset (on the x -axis). The epidemic curve of each outbreak will suggest whether the mode of spread is by a common source or from person to person.

Common source outbreak

This kind of outbreak occurs when people are infected by exposure to the same source of infection. For example, a group of people contract viral hepatitis A because they ate the same contaminated food served during a wedding party. A common source outbreak can be divided into a point common source and a continuous common source:

1. A point common source outbreak occurs when there is a single source that exists for a very short time and all cases have common exposure to it at that particular time.
2. A continuous common source outbreak occurs when there is only one source that provides continuous or intermittent exposure over a longer period of time.

Epidemic curve of a point common source outbreak: the epidemic curve shows a sharp increase of many cases suddenly followed by a rapid decline, although not as rapid as at the beginning of the

epidemic. Another criterion to judge a point common source is that the first and the last cases usually occur within one incubation period.

If the aetiology and the data of the incubation period of the disease are known, the investigators can then roughly estimate the probable time of the initial exposure. This can be done by identifying the peak of the epidemic from the curve and counting back on the x -axis the equivalent of the incubation period. The investigator can also use the first case and count back on the x -axis the duration of the minimum incubation period, which will also give a rough estimate of the time of exposure. In the opposite way, if the information on aetiological agent and incubation period is unknown but the common exposure time is known, the mean incubation is the duration from exposure to the peak of the curve. The shortest incubation period is the duration from the time of exposure to the onset of the first case and the longest incubation period is the duration from the time of exposure to the onset of the last case.

If the aetiology of the disease is not known, but the epidemic curve fits well with a point common source outbreak, the investigator can estimate the average incubation period if he or she knows the times of common exposure.

Epidemic curve for a continuous common source outbreak: the epidemic curve shows an abrupt increase in the number of cases, but instead of having a peak and a decline within one incubation period, new cases persist for a longer time, with a plateau shape instead of a peak before decreasing. In the outbreak of food

Fig. 5.4.3 Dates of illness onset for 163 cases in an outbreak of *Shigella sonnei* infections linked to consumption of imported raw baby corn in Denmark (■) and Australia (□) in August 2007.

From Lewis HC et al., Outbreaks of *Shigella sonnei* infections in Denmark and Australia linked to consumption of imported raw baby corn, *Epidemiology and Infection*, Volume 137, Special Issue 03, pp. 326–34, Copyright © 2009 Cambridge University Press, reproduced with permission, DOI: <http://dx.doi.org/10.1017/S0950268808001829>.

poisoning caused by *Shigella sonnei* infections linked to consumption of imported raw baby corn in Denmark and Australia in August 2007, the peak of the outbreak was observed 6 days after the onset date of the first case and gradually declined (Fig. 5.4.3). All of the cases developed symptoms within a 2-week period, and the outbreak subsided soon after a recall of the implicated batches of baby corn on 17 August 2007 (Lewis et al. 2009). However, if there are many peaks or irregular jagged curves, it suggests an intermittent common source.

Propagated outbreak

A propagated outbreak is caused by transmission from one person to another, and requires direct contact such as touching, biting, kissing, or sexual activity or via vector such as in vector-borne disease outbreak.

Epidemic curve of propagated source outbreak: the epidemic curve shows a slow increase in the number of cases, with progressive peaks approximately one incubation period apart. The investigators might observe an abrupt decrease in new cases, because everyone has already been infected. The span from the first to the last case will also last longer than several incubation periods.

The outbreaks of SARS in Singapore demonstrated the propagated source of transmission beginning from a young female who returned home from Hong Kong. This patient had stayed on the same hotel floor as the index case. She had initially infected many hospital staff before the disease spread for further generations (Kamps and Hoffmann 2003). The outbreak resulted in 238 cases and 33 deaths in a few months (Fig. 5.4.4).

Step 5: testing the hypotheses by an analytic study

In an outbreak of infectious disease, the investigator needs to answer the following questions:

1. What is the aetiology of the disease?
2. What is the source of infection?
3. What is the pattern of spread?
4. What are the risk factors for an individual to get the disease?
5. What are the determinants of the outbreak or the factors which, when combined together, result in the outbreak?

The aetiology of the disease should be derived from the laboratory study. The pattern of spread can be identified by a careful descriptive study. Sometimes it is not as simple as expected, and a descriptive study does not give enough clues. The investigator must carefully re-examine the descriptive information, carry out more active case-finding, and re-analyse the data. The investigator also needs to directly observe the location, lifestyle, and/or behaviour of the cases. These additional investigations usually help the investigator to generate some reasonable hypotheses.

A hypothesis needs to be tested by an analytical study design. The most common is a case-control study. The investigator needs to define the cases and measure the odds of suspected exposed factors found among cases in comparison to the odds of exposure found among appropriately selected controls. The case definition for the analytical study may be more specific than that used for a descriptive study in order to reduce misclassifying non-cases as cases. Conversely, the controls may also need to be tested to avoid classifying non-apparent cases as controls.

An example is the analytic study for identifying risk factors for haemolytic-uraemic syndrome in a large outbreak of Shiga toxin-producing *Escherichia coli* O104:H4 infections in Germany during May 2011 (Buchholz et al. 2011). A matched case-control study was carried out to obtain data from 26 case subjects with the haemolytic-uraemic syndrome and compared to data from

Fig. 5.4.4 SARS cases by date of onset—Singapore, 2003. Reproduced with permission from World Health Organization Regional Office for the Western Pacific, *SARS: how a global epidemic was stopped*, World Health Organization, Western Pacific Region, Manila, Philippines, Copyright © 2006.

81 controls. The investigation revealed ingestion of raw sprouts as the vehicle of infection (matched odds ratio, 4.35; 95 per cent confidence interval, 1.05–18.0). A month after, a similar food poisoning outbreak of the same organism was detected in France (King et al. 2012). The investigators conducted a retrospective cohort study and they found an increased risk of developing the disease among adults who attended the buffet at the Children’s Community Center Event on June 8, 2011 (relative risk, 5.1; 95 per cent confidence interval, 2.3–11.1) in multivariable analysis (Table 5.4.1).

Step 6: environmental or other studies to supplement epidemiological findings

Although an analytical study might be able to confirm a hypothesis, the investigator still needs to find environmental or other evidence to support and explain the epidemiological evidence. In an outbreak of unknown illness in a rural village of Egypt, in which the cases developed severe abdominal pain, persistent vomiting, and generalized weakness, the investigator was able to detect abnormally high blood lead levels among the cases. The analytical study revealed an association between high lead levels in the blood and eating flour from a particular mill factory. The mill implicated in the outbreak was visited, and upon arrival at the mill, the investigators noted a lead smelting pot in the corner of the mill. Lead was used by the miller to attach the crosspiece to the grinding stone. Occasionally the lead would break off and contaminate the flour. The miller reported using about 2 kg of lead per year. Analysis of grain from the mill showed no lead; however, lead was found in flour from the surface of the mill stone and in samples of flour after grinding was complete (Abdel-Nasser 1996).

Table 5.4.1 Multivariable Poisson regression with food-specific relative risks and 95 per cent confidence intervals among adults who attended the buffet at the Children’s Community Center Event, France, June 2011 (n = 64)

Food item	RR	95% CI	P value ^a
Sprouts (any of the 3 kinds)	4.2	1.7–10.0	0.001
Gazpacho (tomato-based cold soup)	2.4	0.9–6.4	0.08
Carrots	2.3	0.8–7.1	0.14
Water (bottled)	2.0	0.8–5.2	0.14
Dip sauce (mayonnaise)	1.7	0.8–3.3	0.15
Lettuce	1.4	0.6–3.6	0.43
Green peppers	0.4	0.1–1.3	0.15

CI, confidence interval; RR, relative risk.

^a All but 1 of the covariables in the presented final multivariable model have *P* values that are non-significant at the 0.05 level. These variables were left in the final model to ensure a sufficient numeric stability of the model.

Reproduced from King LA et al, Outbreak of Shiga toxin-producing *Escherichia coli* O104:H4 associated with organic fenugreek sprouts, France, June 2011, *Clinical Infectious Diseases*, Volume 54, Issue 11, pp. 1588–1594, Copyright © The Author 2012, published by Oxford University Press on behalf of the Infectious Diseases Society of America, by permission of Oxford University Press.

Step 7: establishing the causes of the outbreak

Once the hypothesis has been tested and other necessary studies have been carried out, the investigators can draw their conclusions about the causes of the outbreak. This conclusion is very

important, because action should follow. Many restaurants or factories have been closed because they were implicated as the source of the outbreak. Outbreak investigations are naturally faced with constraints of time and other uncontrolled conditions that do not favour perfect design and methodology. The findings potentially include both random and systematic errors. Before drawing any conclusions, it is important that the investigator carefully examine the weaknesses or limitations of the investigation. In principle, the investigator must identify the cause of the outbreak based on the agreement of the following four pieces of evidence.

Laboratory evidence

The aetiology of the disease is identified in the patients and in the suspected source of infection. If the investigator cannot identify the aetiology from the suspected source, it is still possible to use certain markers to support their conclusions. For example, although a *Vibrio cholerae* type O1 could not be cultured from the drinking water supply of the affected community, the observation of human faecal coliform bacteria in the water helped to indicate that human faeces had contaminated the water.

Clinical evidence

It is necessary to verify that the incubation period and clinical manifestations of cases are compatible with the aetiological agents reported from the laboratory. In the SARS outbreak, most patients developed atypical pneumonia, with rapid progression to respiratory failure, and a fraction of them also had diarrhoea, which could be explained by the findings of SARS coronavirus both in the respiratory tract and stools of patients.

Environmental evidence

Careful investigation of the environment should reveal clues that the causative agent can pass from the source to the cases or the index case to subsequent cases. The investigation of early SARS cases revealed that the index case passed the virus to several people who stayed on the same floor and used the same elevator (Centers for Diseases Control and Prevention 2003).

For an outbreak of food poisoning, a cooking environment that is dirty or located close to the toilet is convincing evidence of food being contaminated by faeces. Crowding in bedrooms is very convincing evidence for a respiratory tract disease outbreak.

Epidemiological evidence

Epidemiological evidence found in the descriptive and analytical studies should clearly explain the following aspects:

- ♦ Pattern of spread, as described by an epidemic curve.
- ♦ Statistical strength of association between exposure and developing the disease.
- ♦ Dose–response relationship, which demonstrates a higher strength of association when the exposure is increasing.
- ♦ Exposure should precede an illness.

It is not uncommon to see some disagreement in the evidence from different sources. In this event, the investigator needs to verify the

validity of each piece of evidence and discuss the data with people who have expertise in that particular area in order to obtain more information and draw a valid conclusion.

Step 8: on-site reporting to and recommendations for concerned authorities

The most important step leading to a timely response is to report the findings to the responsible individuals both at the local and national levels so that they can take appropriate action. Keeping this in mind, the investigators need to complete two tasks before leaving the outbreak area:

1. Complete analysis and data interpretation: leaving the field without completing these tasks will reduce the sense of urgency necessary to finish the work. Data are easier to retrieve when staying in the field rather than instructing field people to send them to the investigation team later.
2. Present the main findings with recommendations: some findings may be very sensitive because they reflect the weaknesses or mistakes of health personnel or other authorities. The investigator needs to select the appropriate approach, either formal or informal, with those responsible. Leaving the field without providing the information that the team obtains from the investigation will be detrimental to other people who could be prevented from becoming ill if the information were known. In many urgent situations, the findings and recommendations might be regularly given to the people responsible during the outbreak investigation process instead of waiting until the end. The investigators also need to present or communicate the findings and recommendations to the national authorities as soon as possible. The recommendations for action should be based on the findings of the investigation. These might include the following aspects.

What can be done to control the outbreak?

With timely investigation, some interventions can be implemented to stop further spread. In the outbreak of measles in a rural community in Peru, measles vaccines were given to children aged between 6 months and 15 years who were not measles cases, regardless of their previous immunization status. Using knowledge about the complication of measles in previous studies, the investigators estimated that the action prevented 87 cases of diarrhoea and 46 cases of pneumonia, and averted five deaths (Sniadack et al. 1999). Outbreaks can be controlled even if the disease aetiology is not known at the moment, but the mode of transmission is known from the investigation. One good example is the early story of the HIV/AIDS epidemic when sexual transmission was identified as a major mode of transmission among sexually active, young gay men.

How to prevent future outbreaks

In many instances, interventions cannot be implemented for the current outbreak, but the findings can be used to set up new practices or policies. These recommendations can help prevent future outbreaks. In Thailand, the recommendation was made to change practices of chicken farming and avoiding direct contact with sick

poultry, which was recommended through the results of the investigation of human H5N1 cases. The Egyptian government, after reviewing the results of the investigation of lead contamination in flour mills, agreed to ban the use of lead in privately owned flour mills (Abdel-Nasser 1996).

How to improve the investigation

The investigator should review the performance of the investigation and identify the weaknesses of the methodology or the field operation so that improvements can be made. These might include a more appropriate case definition, a better investigative design, improved laboratory support, a different team composition, lower costs, a shorter time course, etc.

How to improve surveillance

The best time to evaluate the surveillance system is during an outbreak investigation. In most outbreaks, the investigator must review data from existing surveillance systems. With this direct involvement, the investigator will be able to evaluate the timeliness, completeness, validity of diagnosis, sensitivity of the system, and utilization of the surveillance information. The investigation of human cases of avian influenza (H5N1) in Thailand led to an improved definition of a human case in the areas experiencing an H5N1 virus outbreak in poultry.

Step 9: dissemination of information

In addition to on-site reporting, the investigator should disseminate information to educate the public health community and the general public. There may be many other communities that are also prone to a similar outbreak. The information will raise the awareness of health and government authorities to assess their own situation and implement measures to prevent possible outbreaks. Dissemination of information should occur in a timely manner through weekly or monthly reports. Release of important findings through the mass media is also very useful for educating the public. Before releasing the investigation results through the media, the investigator must ensure that all the facts are delivered in a constructive manner and do not result in blame of any organization. The investigator should also report the investigation results in an international journal or bulletin such as the *Weekly Epidemiological Record* of the WHO, the *Morbidity and Mortality Weekly Report* of the US CDC, the *Eurosurveillance* of the European Centre for Disease Prevention and Control, or the epidemiological bulletin of their own country. This practice is necessary to alert health professionals in other countries and keep them informed of the problem.

In recent years, sharing of information for outbreak detection and control through the Internet and email has been increasingly utilized for timely responses. Telecommunications played an important role in the outbreaks of SARS when the disease was spread rapidly by air transportation to countries on the other side of the world. An example is a teleconference on the clinical features and management of SARS that was held by the WHO, which united 80 clinicians from 13 countries worldwide (World Health Organization Regional Office for the Western Pacific 2006).

Step 10: follow-up to ensure implementation of control measures

Finally, the investigator should follow up the investigation by maintaining close communication with local health authorities. An absence of new cases for at least two incubation periods of the infectious disease under investigation could suggest that the outbreak is subsiding. A good investigator should follow up on the recommendations. An outbreak investigation is a waste of time if sound recommendations have not been implemented. The investigator should learn the reasons why the recommendations were or were not implemented. If the recommendations were implemented, the investigator can also learn the impact by observing the trend of the disease.

Cooperation for international outbreak investigation and preparedness

The world today is especially prone to outbreaks because of frequent cross-border movement, civil war and migration, rapid transportation, international trading, tourism, etc. An outbreak in one country can spread to other countries very easily. For example, in the multi-country SARS outbreak, international travellers were at risk of disease spreading from a single infectious case in a hotel (Centers for Disease Control and Prevention 2003). Ultimately, there were over 8000 cases reported in 26 countries worldwide. The world's experience with the SARS outbreak led to the commitment of countries around the world to improve surveillance and international joint investigation of emerging infectious diseases through new international health regulations that were adopted by the World Health Assembly in 2005.

A massive outbreak of botulism in northern Thailand in March 2006 tested the international capacity to respond to a public health emergency. Botulism poisoning due to contaminated home-canned bamboo shoots caused illness in 209 villagers, of whom 134 persons were hospitalized and 42 required mechanical ventilation. A global search for botulinum antitoxin began, involving international agencies, embassies, national laboratories, airlines, and commercial organizations in seven countries. Sufficient antitoxin was obtained from four sources for treatment of 90 patients, with a delay in treatment of 5–9 days from time of exposure. Rapid local outbreak detection and an effective international response likely prevented mortality and additional morbidity (World Health Organization 2007).

An outbreak anywhere in the world must therefore be treated as a threat to all countries. It is important for each country to build up its capacity for surveillance, outbreak preparedness, and investigation. In addition to the US CDC Epidemic Intelligence Services, over 50 countries have started training programmes and established a medical detective unit that is ready to investigate all kinds of outbreaks. These training programmes are known by different names, such as the Field Epidemiology Training Program (FETP) or the Field Epidemiology and Laboratory Training Program (FELTP), and The European Programme for Intervention Epidemiology Training (EPIET). Recently, ten countries under the Association of South East Asian Nations

(ASEAN) joined China, Japan and South Korea to establish the ASEAN+3 Field Epidemiology Training Network (ASEAN+3 FETN) to foster national and regional capacity-building in disease surveillance and outbreak responses. The WHO has supported the establishment of the Global Outbreak Alert and Response Network, a technical collaboration of existing institutions and networks to pool human and technical resources for the rapid identification, confirmation and response to outbreaks of international importance. It is a wise investment, and a commitment that is needed by the international community for information exchange and collaborative investigation of outbreaks in a timely manner.

Conclusion

Outbreak investigation is an essential function of public health professionals who care for the well-being of the community. It is an opportunity to gain new knowledge of diseases and to discover the weaknesses of current public health practices and systems. A good public health professional must always be alert to the possibility of outbreaks. Normal surveillance systems or unofficial sources, such as the mass media, can be a good source for detection of an outbreak. Before starting field investigations, investigators should organize the team, review previous knowledge, prepare the technical and management aspects, and start the investigation as soon as possible. The investigation can be conducted by following the ten steps outlined in this chapter. The investigation usually starts by confirming the existence of the outbreak, verifying the diagnosis, gathering case information, descriptive epidemiology, formulating and testing the hypothesis when necessary, conducting environmental surveys to supplement epidemiological evidence, and providing timely on-site reporting of the findings, with practical recommendations to local and national responsible authorities. Competent outbreak investigators combine sound scientific knowledge and good management skills. Direct participation in conducting the investigation is needed to gain the necessary skills. A good investigator should be a field-oriented person with strong levels of perseverance, scepticism, and common sense. The investigator should not end his or her work with the report, but should follow up on the recommendations and continue vigorous surveillance of the problem. In the future, increasing joint international investigations will be needed. Rich countries and resource-limited countries need to collaborate to detect and stop outbreaks before they get out of control. Through this cooperation, the world will be a safer place amidst the threat of old and emerging disease outbreaks.

Case–control studies

Noel S. Weiss

Introduction to case–control studies

In 1971, Herbst and colleagues (Herbst et al. 1971) reported that mothers of seven of the eight teenage girls diagnosed with clear cell adenocarcinoma of the vagina in Boston, Massachusetts, during 1966–1969 claimed to have taken a synthetic hormone, diethylstilbestrol, while pregnant. None of the mothers of the 32 girls without vaginal adenocarcinoma, matched to the cases' mothers with regard to hospital and date of birth, had taken diethylstilbestrol during their pregnancy. Within a year, a New York study of five girls with and eight girls without vaginal cancer obtained similar results (Greenwald et al. 1971). The introduction of pre-natal diethylstilbestrol use into obstetric practice in the United States during the 1940s and 1950s followed by the appearance of this hitherto unseen form of cancer some 20 years later supported a causal connection between *in utero* exposure to diethylstilbestrol and vaginal adenocarcinoma. The means by which *in utero* diethylstilbestrol exposure might predispose to the occurrence of clear cell vaginal adenocarcinoma was unknown in 1971. (It is now believed that diethylstilbestrol acts by interfering with normal development of the female genital tract, resulting in the persistence into puberty of vaginal adenosis in which adenocarcinoma can arise.) Nonetheless, a causal inference was made at that time by the Food and Drug Administration, which specified pregnancy as a contraindication for diethylstilbestrol use.

The investigation by Herbst et al. (1971) was a case–control study: a comparison of prior exposures or characteristics of ill people (cases) with those of people at risk for the illness in the population from which the cases arose. Generally, the prior experience of people at risk is estimated from observations of a sample of that population (controls). A difference in the frequency or levels of exposure between cases and control—that is, an association—may reflect a causal link.

A case–control, cohort, or any other form of non-randomized study has the potential to identify associations that are not causal, either because of chance or because of the influence of some other factor associated with both the exposure and outcome. Even so, the evidence that is provided by well-performed case–control studies can carry great weight when evaluating the validity of a causal hypothesis. Indeed, a number of causal inferences have been based largely on the result of case–control studies. These include, in addition to the diethylstilbestrol–vaginal adenocarcinoma relationship, the connection between aspirin use in children and the development of Reye's syndrome, and the use of absorbent tampons and the incidence of toxic shock syndrome.

One of the criteria used to assess the validity of a causal hypothesis is the strength of the association between exposure and

disease, usually as measured by the ratio of the incidence rate in exposed and non-exposed people. In most case–control studies, it is not possible to measure incidence rates in either of these groups. Nonetheless, from the frequency of exposure observed in cases and controls, it is usually possible to estimate closely the ratio of the incidence rates.

To understand how this can be done, consider a cohort study in which exposed and non-exposed people are followed for a certain period of time. Table 5.5.1 summarizes their experience with regard to a particular disease.

The cumulative incidence of the disease in exposed and non-exposed people over a given period of follow-up is $a/(a + b)$ and $c/(c + d)$, respectively. The relative risk (RR) is the ratio of these:

$$RR = \frac{a / (a + b)}{c / (c + d)}.$$

If the incidence of the disease is relatively low during the follow-up period in both exposed and non-exposed people, then a will be small relative to b and c will be small relative to d . Therefore:

$$RR = \frac{a / (a + b)}{c / (c + d)} \approx \frac{a / b}{c / d} = \frac{a / c}{b / d}.$$

In this expression, the numerator (a/c) is the odds of exposure in people who develop the disease and the denominator (b/d) is the odds exposure in people who remain well. Therefore:

$$\text{Odds ratio (OR)} = \frac{a / c}{b / d}.$$

The numerator can be estimated from a sample of cases, and the denominator can be estimated from a sample of non-cases. Neither estimate is influenced by the proportion of cases among the subjects actually chosen for study.

In the hypothetical example shown in Table 5.5.2, assume that 100 of 10,000 people exposed to a particular substance or organism

Table 5.5.1 Data layout for a hypothetical cohort study involving a dichotomous exposure variable

Cases	Diseased	Non-diseased	Total
Exposed	a	b	$a + b$
Non-exposed	c	d	$c + d$

Table 5.5.2 Depiction of data from a hypothetical study of a possible association between exposure and disease in an entire population

Cases	Diseased	Non-diseased	Total
Exposed	100	9900	10,000
Non-exposed	300	89,700	90,000

Table 5.5.3 Depiction of the results of a case-control study conducted in the population from which Table 5.5.2 was derived

Cases	Diseased	Non-diseased
Exposed	$100 \times 0.5 = 50$	$9900 \times 0.01 = 99$
Non-exposed	$300 \times 0.5 = 150$	$89,700 \times 0.01 = 897$

developed a disease, compared with 300 of 90,000 non-exposed people:

Therefore:

$$RR = \frac{100 / 10000}{300 / 90000} = 3.00.$$

If a case-control study had been carried out in this population, in which 50 per cent of the cases were included but only 1 per cent of the non-cases, then the results shown in Table 5.5.3 would have been obtained.

In many studies, controls are chosen as they were in this example; that is, from people who have not developed the disease by the end of the same time period during which other people (the cases) have become ill. In such studies, the less common the disease in both the exposed and non-exposed people during the period, the better the odds ratio will estimate the ratio of cumulative incidence. In the example, only 0.1 per cent and 0.33 per cent of exposed and non-exposed people, respectively, developed the illness: so, the relative cumulative incidence and odds ratio are nearly identical (3 versus 3.02). However, it is also possible to choose controls from people free of disease only until the corresponding cases have been diagnosed; a person can appear in the study first as a control and later as a case. If this approach is used, the odds ratio will be a valid estimate of the ratio of incidence rates (i.e. cases divided by person-time at risk) irrespective of the disease frequency (Greenland and Thomas 1982; Pearce 1993).

Retrospective ascertainment of exposure status in cases and controls

Epidemiological studies seek to obtain information on exposures present during an aetiological relevant period of time; that period varies across aetiological relationships. For example, although excess consumption of alcohol predisposes to both motor vehicle injuries and cirrhosis of the liver, it does so during considerably different time intervals before the occurrence of the injury or the onset of the illness, respectively.

Some case-control studies are nested within cohort studies in which specimens (e.g. blood or urine) have been obtained before

diagnosis on all cohort members, but have not yet been analysed for the exposure(s) in question. When these analyses are carried out on cohort members who developed a particular illness and on controls selected from the cohort, the results obtained are not influenced by the events occurring after the diagnosis of the illness. (To avoid the possibility of occult illness in cases influencing levels of a suspected aetiological factor, many studies of this type exclude from the analyses specimens obtained in the period before diagnosis that might correspond to the preclinical stage of disease.) Also, among the large majority of case-control studies in which exposure status is not measured until the illness or injury has been diagnosed, some are concerned only with an exposure or characteristic that would have been the same at all times in a person's life. This is true for a genetically determined characteristic such as ABO blood type or the absence of glutathione transferase M₁ activity (an enzyme that metabolizes several potentially carcinogenic constituents of cigarette smoke). Clearly, these studies are no less valid for having had to measure exposure in retrospect.

However, most case-control studies are required to consider explicitly how best to assess in retrospect the subjects' exposure status during one or more possible aetiological relevant time periods. Possible sources of exposure data include interviews or questionnaires, available records, and physical or laboratory measurements.

Interviews or questionnaires

For many exposures, a subject's memory is an excellent window to the past. A number of important aetiological relationships have been identified through interview-based case-control studies. Generally, study participants will report longer-term and more recent experiences with greater accuracy than shorter-term and more distant ones. Attention to the ways in which questions are asked (White et al. 2008), along with the use of visual aids when appropriate (e.g. pictures of medicines, or containers of household products, and calendars for important life events to enhance recall of the timing of other exposures), will maximize the accuracy of the information received. These efforts, along with the use of the same questions for cases and controls asked in the same way, will also minimize the potential for bias that could result from the subject's or interviewer's awareness of case or control status.

One advantage of exposure ascertainment via interview or questionnaire is that information can be sought for multiple points in the past. It is possible that a given exposure plays an aetiological role only if present at a certain age, for a certain duration, or at a certain time in the past. Because there is often little guidance before a study starts that suggests the most relevant age, length, or recency, key exposures are often elicited throughout much of the subject's lifetime. However, care must be taken not to include exposures that took place after the illness began. An instructive example is provided by Victora et al. (1989) in a case-control study of infant death from diarrhoea as related to the type of feeding. These investigators asked mothers whether their child was or was not being breastfed immediately before the onset of the fatal illness (mothers of controls were queried about type of feeding prior to a comparable point in time). Mothers were also asked if subsequent to the onset of the illness there had been any changes in the type of feeding; following the development of diarrhoea, many children were switched to formula and cow's milk. Relative to infants who were solely breastfed, those who were supplemented with

powdered or cow's milk prior to their illness had about four times the risk of diarrhoeal death. However, the authors showed that if one inappropriately considered the feeding method that was present during the illness, about a 13-fold increase in risk associated with supplementation would have been estimated.

Records

Case-control studies have exploited the presence of vital, registry, employment, medical, and pharmacy records, to name a few, as a means of obtaining information on exposures. However, because the information contained in the records is usually assembled for purposes other than epidemiological research, they may not provide precisely the information desired by the epidemiologist. For example, a death certificate or an occupational record may state an individual's job, but often not his or her actual exposure to the substance(s) of interest to the study. A pharmacy record will indicate a prescription having been filled, but not necessarily whether the patient took the medication on a given day, or took it at all. This sort of imprecision will impair a study's ability to discern a true association between an exposure and a disease—the greater the imprecision, the greater the impairment.

Nonetheless, some very strong associations have been identified through record-based case-control studies. For example, Daling et al. (1982) conducted a tumour registry-based case-control study to test the hypothesis that homosexual men have a relatively high incidence of anal cancer. Although registry data do not specify a man's sexual preference, they do contain information regarding his marital status. The investigators found that three times more men with anal cancer than controls (men with colon or rectal cancer) had never been married. Being single is far from a perfect predictor of homosexuality, of course. Nonetheless, the presence of such a large case-control difference, given the very poor means of gauging the relevant exposure, was a stimulus to conduct interview-based studies that could elicit information regarding sexual history with greater precision. The latter studies showed an exceedingly strong association between anal cancer in men and a history of sexual intercourse with another man (Daling et al. 1987).

In case-control studies in which medical records are used to characterize exposure status, care must be taken to restrict the information obtained to that which precedes the case's diagnosis (and the presence of symptoms, if any, that led to the diagnosis). The records of controls must be truncated at similar points in time. Without this safeguard, it is possible that bias will arise because there are systematically more records available to review on cases than controls; the case's illness may have stimulated an enquiry by medical personnel into his or her past, whereas no corresponding enquiry would necessarily have occurred for control subjects.

Physical and laboratory measurements

The recognized limitations of interviews and records in characterizing a variety of potentially relevant exposures have stimulated the conduct of epidemiological studies that use laboratory and other methods of measurement. A woman cannot tell an investigator the level of her reproductive hormones, the concentration of various micronutrients in her blood, or whether her cervix is infected with human papillomavirus, but laboratory tests can. Unfortunately, such tests tell us what these things are only at the

time that the specimens have been obtained. For some exposures, there will be a high correlation between the measured level following case and control identification, and that which was present during the aetiologically relevant time period. For example, lead enters and does not leave the dentine of teeth. Therefore, in young school-age children, lead dentine levels are an indicator of cumulative lead exposure, a good portion of which could be relevant to the development of intellectual impairment and other adverse neurological outcomes. In contrast, one would not rely on serum levels of reproductive hormones of postmenopausal cases of breast cancer and controls to indicate what their premenopausal levels were, much less their hormonal status during their very early reproductive years (at which time the hormones may be exerting their greatest impact on future risk of breast cancer).

Case definition

Ideally, the cases in a case-control study would comprise all (or a representative sample of) members of a defined population who develop a given health outcome during a given period of time. For studies of disease aetiology, that outcome is the disease incidence. For studies that seek to determine the efficacy of early disease detection or treatment, the outcome generally is the occurrence of complications of the disease or mortality; such studies have been described in detail elsewhere (Selby 1994; Weiss 1994), and will not be covered any further here.

The population from which cases are to be drawn may be defined geographically or on the basis of other characteristics such as membership in a prepaid healthcare plan or an occupational group. The identification of all newly ill people in a defined population can be facilitated by the presence of a reporting system such as a cancer or malformation registry that seeks to accomplish this identification for other purposes. Occasionally, care for the condition being studied may be centralized, so that it will be necessary to review the records of only one or a few institutions to identify all cases in the population in which those institutions are located. However, in many instances, it is not feasible to identify all cases that occur in a given population; therefore, case-control studies are often based on cases identified from hospital records, or from the records of selected providers from whom patients had sought healthcare. The study by Herbst et al. (1971) on vaginal adenocarcinoma was of this type. Whether or not the cases are derived from a defined population, it is necessary that they be drawn in an unselected manner with regard to exposure status; for example, by including in the study all otherwise eligible cases diagnosed or receiving care during a defined time period.

Although the goal of a case-control study of aetiology is to enrol incident cases, under some circumstances it may be necessary to enrol prevalent cases at a particular point in time, irrespective of when each one's illness had begun. For some conditions, the date of occurrence may simply not be known; for example, in the absence of very close sero-monitoring, one generally cannot determine when a person acquired an HIV infection. Furthermore, for uncommon diseases of long duration, an incidence series may yield too few cases for meaningful analysis. The disadvantages of using prevalent cases in a case-control study relate in part to the added problems of accurate exposure ascertainment. For prevalent conditions whose date of diagnosis is known, pre-illness exposure information on study subjects

must be obtained for more distant points in the past, on average, than would be necessary for an incident series. For prevalent conditions whose date of occurrence is unknown (e.g. HIV infection), there will be uncertainty as to the best point in time before which one should elicit exposure information. Also, by studying people remaining alive with a given condition, one is simultaneously studying not only aetiological factors but also those that influence survival from the condition.

Ideally, the criteria used to identify and select individual cases for study should be objective with high sensitivity and specificity for the disease. Specificity is of particular concern, because the inadvertent inclusion of people without disease into the case group will generally obscure any true association with the exposure. With this in mind, in the case-control study of Reye's syndrome and antecedent analgesic use conducted by the Centers for Disease Control (Hurwitz et al. 1985), only cases with a substantial degree of neurological impairment (stage 2 or higher) were included. The use of this criterion minimized the chances that children with a disease other than Reye's syndrome, which generally would have a lesser degree of severity, would be included in the case group. It also was intended to serve as protection against selective misclassification of Reye's syndrome based on knowledge of exposure status, because the hypothesis of the association of aspirin with Reye's syndrome was well known by the time the study took place. Conceivably, the knowledge that the child had consumed aspirin could have led some doctors to diagnose Reye's syndrome in cases with an atypical illness.

Control definition

Occasionally, the proportion of ill people who have had a specific exposure is so high, unequivocally more than would be expected in the population from which they were derived, that the presence of an association (although not its magnitude) can be surmised from a case series alone (Cummings and Weiss 1998). For example, when it was learned that all cases of a form of pneumonia that was epidemic in Spain in 1981 had ingested adulterated rapeseed oil, a causal inference was drawn, leading to efforts to eliminate further use of this oil. This action was taken before any formal comparison of cases with controls was made (Tabuenca 1981).

However, in the vast majority of instances, an explicit control group is needed to estimate the frequency and degree of exposure that would have taken place among cases in the absence of an exposure-disease association. An ideal control group would be one that comprises individuals:

1. Selected from a population whose distribution of exposure is that of the population from which the cases arose.
2. Who are identical to the cases with respect to their distribution of all characteristics: (a) that influence the likelihood and/or degree of exposure, and (b) that, independent of their relation to the exposure, are also related to the occurrence of the illness under study or to its recognition.
3. In whom the presence of the exposure can be measured accurately and in a manner that is identical to that used for the cases.

If these criteria are not met in a particular study, then selection bias, confounding, or information bias, respectively, will be present.

Minimizing selection bias

If the cases identified in the study are all or a sample of those that occurred in a defined population, one can seek to achieve comparability by choosing as controls people sampled from that same population. For geographically defined populations, a number of different sampling methods have been used, including random digit dialling of telephone numbers, area sampling, neighbourhood sampling, voters' lists, population registers, motor vehicle licences, and birth certificates, among others. When cases are members of a prepaid healthcare plan who develop an illness or injury, a sample of people who were members of the health plan when the illness or injury occurred can serve as controls. When cases are ill or injured members of an employed population, controls can be selected from this same population.

Enumeration of the defined population from which the cases arose may require an innovative approach. For example, Smith et al. (2001) identified recreational boating fatalities in Maryland and North Carolina among persons 18 years and above during 1990–1998, seeking to determine the presence and magnitude of an association with alcohol consumption. Of 221 fatal cases on whom blood alcohol levels were measured, 55 per cent tested positive. To provide a basis for comparison, the investigators devised a plan to randomly sample recreational boats on the waterways of the two states, and then to obtain a breath sample for alcohol testing from the boat operator and a random sample of any passengers aboard ($n = 3943$). Only 17 per cent of these persons chosen as controls had a positive result, and the disparity between cases and controls grew with increasing alcohol levels.

If cases have not been selected from a definable population at risk for the disease, but from people treated for a particular illness at one or a few hospitals or clinics, then selection bias may be introduced if controls are not chosen from people who, had they developed the illness under study, would have received care at these hospitals or clinics, and if people who do and do not receive care from these sources differ with regard to the frequency or level of exposure. Therefore, when cases are chosen from a narrow range of healthcare providers, controls are often chosen from other ill people treated by these providers. Such ill controls may also be used if, irrespective of the source of the cases, there is no feasible way to sample from the population at large, or if sampling from the general population would result in a substantial level of non-response or information bias. For these reasons, in some studies of fatal illness, exposures in people with a given cause of death are compared with exposures in a sample of people who died from other causes.

However, the choice of ill or deceased controls can itself give rise to selection bias if the illnesses (causes of death) represented in the control group are in some way associated with the exposure of interest. For example, ill or recently deceased people tend to have been smokers of cigarettes more often than other people (McLaughlin et al. 1985), because smoking is associated with a variety of causes of illness and death. Because smoking histories of ill people overstate the use of cigarettes in the population from which the cases arose (even if that population cannot be defined), the odds ratio associated with smoking based on the choice of ill people as controls will be spuriously low.

To minimize selection bias related to having chosen ill or deceased controls, an attempt can be made to omit potential controls

with conditions known to be related (positively or negatively) to the exposure. For example, in the analysis of a hospital-based case-control study of bladder cancer and earlier use of artificial sweeteners, the investigators excluded from their control group people who were admitted to hospital for obesity-related diseases (Silverman et al. 1983). They showed that without this restriction, the control group would have a spuriously high proportion of users of artificial sweeteners relative to the population from which their cases had actually come. This approach will succeed to the extent that one judges correctly which conditions are truly exposure related, and how accurately the presence of those conditions can be determined. For many exposures, this may pose little problem, and judicious exclusion will yield a control group capable of providing an unbiased result. For others, such as cigarette smoking or alcohol consumption, it has been shown that admitting diagnoses or statements of cause of death are incapable of identifying all people with illnesses related to these exposures (McLaughlin et al. 1985).

Some case-control studies simply compare exposure status among subgroups of patients with the same outcome. For example, Laumon et al. (2005) obtained blood samples of 10,748 drivers involved in fatal road accidents in France during 2001–2003, and had these analysed for a metabolite of cannabis. The investigators contrasted the proportion testing positive between drivers judged to have been at fault for the crash ('cases') and drivers judged not to have been at fault ('controls'). The results of such a study will be valid when it is possible to identify those drivers who were at fault. To the extent that this is not possible, the misclassification that ensues will tend to make the size of the observed association smaller than the true one.

Occasionally, controls are chosen from individuals who are tested for the presence of the disease under study and are found not to have it. For example, people demonstrated to have coronary artery occlusion on coronary angiography have been compared with angiography patients without occlusion with regard to potential risk factors (Thom et al. 1992). As another example, the prior use of oral contraceptives was compared between women diagnosed with venous thromboembolism and women seen at the same institution for suspected venous thromboembolism who were diagnosed as not having this condition (Bloemenkamp et al. 1999). It may be relatively inexpensive to select controls from people who receive the same diagnostic evaluation as do cases, and it is also possible to achieve case-control comparability with regard to the choice of a healthcare provider (and the correlates of that choice). This approach can have an impact on the study's validity if the frequency or degree of exposure differs between otherwise comparable members of a population who do and do not receive the test. It will increase the validity if the disease being investigated is generally asymptomatic, and so would not be detected in the absence of testing. Thus, the relation of the use of oral contraceptives with the incidence of *in situ* cancer of the cervix is best studied in women who have undergone cervical screening, by comparing oral contraceptive use between cases of *in situ* cancer and women with a negative screen. This is because:

- ♦ In most societies, women who use oral contraceptives are screened more commonly than women who do not.
- ♦ *In situ* cancers are asymptomatic and will not be identified in the absence of cervical screening.

Therefore, if controls are chosen from women in general, who may or may not have received cervical screening, an apparent excess of oral contraceptive users would be present among cases of *in situ* cancer even if no true association were present.

However, the choice of test-negative controls can detract from a study's validity if the large majority of the people who develop the disease would soon be diagnosed whether or not the test was administered. There was a controversy in the late 1970s regarding the suitability, in case-control studies of postmenopausal oestrogen use and endometrial cancer, of a control group restricted to women with no evidence of cancer on endometrial biopsy. Among women without endometrial cancer, oestrogen use differs greatly between those who have and have not undergone biopsy, because oestrogen use predisposes to uterine bleeding of non-malignant causes, which often leads to endometrial biopsy. Those investigators who believed that there was a great prevalence of occult endometrial cancer in the population suggested that the optimal control group ought to be women undergoing endometrial biopsy and found not to have cancer (Horwitz and Feinstein 1978). However, the majority of the investigators believed that no such large pool of prevalent, occult disease existed, and that choosing biopsy-negative controls would lead to a spuriously high estimate of oestrogen use in the population at risk, and thus, a spuriously low odds ratio (Shapiro et al. 1985).

No matter how controls are defined in a case-control study, selection bias may be introduced to the extent that exposure information is not obtained on all who have been selected to participate. The magnitude of this bias will increase in relation to the frequency of missing data and the degree to which exposure frequencies or levels differ between study subjects on whom exposure status is and is not known. The problem of incomplete ascertainment of exposure on study subjects is particularly common in interview- or questionnaire-based case-control studies. Strategies for minimizing the degree of non-response in case-control studies are discussed in detail elsewhere (White et al. 2008).

Minimizing confounding

Characteristics of confounding variables in case-control studies

Confounding occurs when the estimate of the relationship between an exposure and a disease is distorted by the influence of another factor. In any study design, confounding will occur to the extent that the other factor is associated with both the exposure (although not as a result of the exposure) and the disease or its recognition. In case-control studies alone, a factor may confound even if it is not associated with an altered risk of disease, if the proportions of cases and controls vary across levels or categories of the factor. For example, in a collaborative study of ovarian cancer and use of oral contraceptives (Weiss et al. 1981), an attempt was made to identify and interview all incident cases over several years in two American populations. In one of the populations (western Washington state), several controls per case were interviewed, whereas the control-to-case ratio in the other (Utah) was 1:1. Because oral contraceptive use was more common among women in Washington than in Utah, failure to take into account the state of residence in the analysis (e.g. by adjustment) would have led to a spuriously high estimate of the frequency of oral contraceptive use by controls relative to that by the cases.

Means of controlling for confounding

One straightforward way of preventing confounding is to restrict cases and controls to a single category or level of the potentially confounding variable. For example, in their study on physical activity and primary cardiac arrest, Siscovick et al. (1982) excluded people with conditions, such as clinically recognized heart disease, that could both predispose to cardiac arrest and might be expected to alter level of activity. A second way is to obtain information on exposures or characteristics that may differ between cases and controls, and then make statistical adjustments for those that are also found to be related to the exposure or characteristic under investigation (Rothman et al. 2008).

Finally, it is possible to match one or more controls to each case's category or level of a potentially confounding factor. It is appropriate to match if:

1. The variable is expected to be strongly related to both the exposure and disease. Thus, in a case-control study of breast cancer and use of hair dye, it would make sense to match on gender (if the study has not already been restricted to women) because use of dye is more common among women than men in most cultures. Although confounding by gender could be prevented even without matching by adjustment in the analysis, the statistical precision of the unmatched study would be substantially reduced relative to that of a case-control study having a more similar proportion of female cases and controls.
2. Information on possible matching variables can be obtained inexpensively. There are some means of control selection in which information regarding some confounders can be obtained at no cost. For example, from voters' lists or prepaid health-plan membership records, it would generally be possible to choose directly one or more controls who were identical to a given case's age. Conversely, if a population sampling scheme such as random digit dialling were being employed, the age of the respondent would not be known in advance of approaching him or her. Rather than omitting already contacted controls who did not match a particular case's age, the matching can be done much more broadly; additional control for finer categories of age can be accomplished in the data analysis.
3. Information on exposure status cannot be obtained inexpensively. The higher the cost of exposure ascertainment, the greater the incentive to limit the number of control subjects to the number of cases. Case-control differences regarding confounding factors particularly will reduce the statistical power of a study that does not have a surplus of controls. Enriching the group of controls selected with people more similar to the cases with regard to confounding factors (i.e. matching) can prevent this loss of statistical power.

In case-control studies of genetic characteristics as possible aetiological factors, some investigators have used a matched design in which a specific type of relative (e.g. parent, sibling, or cousin) is chosen as a control for each case (Yang and Khoury 1997; Witte et al. 1999). This approach has the advantage of minimizing potential confounding by other genetic characteristics with which the one of interest is associated. However, it has the disadvantage of excluding a possibly large fraction of cases for whom there is no relative available of the type needed to provide a sample for genetic analysis.

Table 5.5.4 Data layout in a hypothetical matched case-control study involving a dichotomous exposure variable

Cases	Controls	
	Exposed	Non-exposed
Exposed	<i>a</i>	<i>b</i>
Non-exposed	<i>c</i>	<i>d</i>

It should be remembered that matching alone is not sufficient to eliminate a variable's confounding influence: failure to consider a matching variable in the analysis of the study can lead to a biased result (Rothman et al. 2008). Analyses of studies that have matched controls to cases on a given characteristic can adjust for that characteristic as if no matching had taken place. Alternatively, these analyses can explicitly consider cases and controls as matched sets. In the instance of matched case-control pairs and a dichotomous exposure variable, Table 5.5.4 could be constructed.

Only the *b* pairs in which the case was exposed but not the matched control, and the *c* pairs in which the reverse was true, would enter the analysis. The odds ratio would be calculated as *b/c*. When there is more than one control per case, the matched odds ratio can be calculated as well (Breslow and Day 1980).

Minimizing information bias

For case-control studies in which information on exposure status is sought via an interview or questionnaire, the chief safeguards against information bias entail asking questions about events that are salient to the respondent, that are framed in an unambiguous way, and that are presented identically to both cases and controls. Employment of these safeguards, however, will not prevent differential accuracy of reporting between cases and controls in all circumstances. Some past exposures or events will simply be more salient to people with an illness, who might have dwelled on possible reasons for its occurrence, than to people without that illness. Other exposures may be viewed as socially undesirable, and there may be a difference between cases and healthy controls in their willingness to admit to them. If the anticipated difference in the quality of information between cases and otherwise appropriate controls is too great, a control group that is less than ideal in other respects may be selected instead so as to minimize the potential for information bias. For example, some studies of prenatal risk factors for a particular congenital malformation that utilize maternal interviews as the source of exposure data have selected as controls infants with other malformations (Rosenberg et al. 1983). This control group will provide a more valid result than a control group that consists of infants in general if mothers of malformed and mothers of normal infants report prenatal exposures to a different degree even in the absence of an association, and the exposure in question is not associated with the occurrence of the malformations present in control infants.

Similar reasoning led Daling et al. (1987), when conducting their case-control study on anal cancer and a history of anal intercourse, to eschew the geographic population from which their cases had arisen as a sampling frame for controls. They feared that interviews that sought information about prior anal intercourse might be more complete among men with cancer than men in the

population at large. Thus, they chose as controls men with a cancer of a different site (colon), which they believed was unlikely to have been aetiologically related to prior anal intercourse.

When the exposure under consideration is sufficiently imprecise or is open to subjective interpretation, there may not be any control group that will provide information comparable to that provided by cases. An instructive example comes from a case-control study on Down's syndrome (Stott 1958), conducted shortly before the chromosomal basis for the aetiology of this condition had been learned. The study sought to determine whether emotional 'shocks' during pregnancy might be a risk factor. The author interviewed mothers of children with Down's syndrome with regard to the occurrence of a 'situation or event [that would be] stress- or shock-producing if this would have been its expected effect on an emotionally stable woman'. Identical interviews were administered to mothers of normal children, and also to mothers of children with mental retardation who did not have Down's syndrome. Even though it is not possible that an emotional shock in pregnancy could play any aetiological role in a condition already determined at conception, a far higher proportion of mothers of cases of Down's syndrome reported an emotional shock than did mothers of normal controls (RR estimated from the data, 17.0). The use of other children with mental retardation as controls only partially reduced the spuriously high relative risk, to a value of 4.3.

When conducting an interview-based study of a rapidly fatal disease, or a disease that impairs a person's ability to provide valid interview data, it is necessary to obtain information from at least some surrogate respondents; typically, these respondents are close relatives of the cases. In general, for purposes of comparability, similar information ought to be obtained from surrogates of controls, even though the control would be expected to provide more accurate data. Results of case-control studies based on exposure information provided by surrogate respondents need to be interpreted with particular caution. Although by no means present in every instance (Nelson et al. 1990; Campbell et al. 2007), there can be a large difference in the validity of the responses given by case and control surrogates. For example, Greenberg et al. (1985) investigated the basis for an apparent strong association between cancer mortality and 'nuclear' work among employees of a naval shipyard, which had been found during a comparison of work histories provided by surrogates of men who died from cancer and of those who died of other conditions. They observed that, regarding work in the nuclear part of the industry, surrogates of the cases generally provided information similar to that contained in employment records of the shipyard; in contrast, the surrogates of controls substantially misclassified the nature of their relatives' jobs as not involving radiation. Using the data provided by employment records, which included individual radiation dosimetry, little or no association was found between cancer mortality and radiation exposure received at the shipyard (Rinsky et al. 1981).

What was undoubtedly a spuriously negative association was found in a case-control study of lung cancer and passive cigarette smoking that used, for one analysis, information obtained from surrogate respondents (Janerich et al. 1985). In this analysis, the relative risk of lung cancer among non-smokers associated with a spouse's having smoked—0.33 (i.e. a 67 per cent reduction in risk)—would seem almost certainly due to a spurious minimization or the denial of smoking by spouses of cases, who may have feared their habit caused their spouse to develop lung cancer.

In most interview-based case-control studies, information is not sought from cases until days to months have elapsed following the diagnosis of their condition. These persons are queried regarding exposures that occurred during what is presumed to be the aetiologically relevant period prior to diagnosis. For controls, for whom there is no 'diagnosis' date, what is the appropriate time frame in which to focus the questions that are asked of them? If exposures that occurred some time in the past, or that occurred over an extended period, are most likely to be relevant, controls are generally asked about events during the same calendar time as the cases. However, when studying exposures that could act acutely to lead to illness, having the case recall events immediately prior to illness and the control do the same for the corresponding time in the past may lead to bias: only the cases will have the onset of their illness to help in recalling events that took place shortly prior to that time. This difference could lead to relatively more complete ascertainment of exposure among cases.

In response to this concern, some case-control studies investigating potentially rapidly acting exposures query controls about the time period prior to the date of interview instead of the date of their case's diagnosis (or, in an unmatched study, the date of a typical case's diagnosis). So, in a study of risk factors for meningococcal disease in adolescents (Tully et al. 2006), cases were asked about events during the 2 weeks prior to diagnosis (which occurred, on average, 53 days before the interview) and controls about events during the 2 weeks just prior to the interview itself. The investigators felt that the plausibility of case-control comparability on recall of exposures involved in transmission (e.g. 'intimate kissing with multiple partners') would be greater using this approach than one in which the controls were asked about a 2-week period ending 53 days prior to the interview. However, although a sound approach when trying to estimate the short-term influence of many exposures, this strategy can backfire if recall of an exposure diminishes over time to the same degree in cases and controls. For example, in the study of meningococcal disease, a far smaller proportion of cases than controls reported attending religious observances during their respective 2-week intervals (adjusted odds ratio = 0.1, 95 per cent confidence interval = 0.02–0.6). Almost certainly, this difference had more to do with relatively poorer recall of churchgoing among cases (who had to think back some 2 months) than to a genuine salutary effect of church attendance on the incidence of meningococcal disease.

Incomparable assessment of exposure status between cases and controls is not confined to interview- or questionnaire-based studies. Most laboratory-based studies seek to prevent this by testing samples blind to case and control status. If feasible, it is desirable to also carry out this blinding for studies in which exposure is to be determined from medical or other records. However, there are instances in which the nature of the information available in records has already been influenced by whether the subject is a case or a control. For example, it was found that among 100 infertile women who underwent laparoscopy (Stratby et al. 1982), 21 had endometriosis. Only 2 per cent of the 200 women who underwent laparoscopy for another indication, tubal ligation, were noted in the procedural records as having endometriosis. However, the interpretation of this association is unclear, because the identification and/or recording of endometriosis in cases and controls (women undergoing tubal ligation) may well have been incomparable—only in the infertile women was the laparoscopy

expressly done as a diagnostic tool to investigate the possible presence of conditions such as endometriosis.

Estimating attributable risk from results of case–control studies

Occasionally, a case–control study identifies a large odds ratio relating an exposure to a disease, and for this and other reasons, a causal influence of the exposure may be suspected. The decision to seek to limit or eliminate that exposure requires weighing its negative and positive consequences. This weighing must be done in absolute, rather than in relative terms, because the same relative increase (or decrease) in risk is of far greater consequence for common than for rare outcomes. The absolute increase in the risk of disease believed to be due to a dichotomous exposure, sometimes referred to as the ‘attributable risk’ (AR), can be estimated directly from data gathered in cohort studies or randomized trials as the difference between the incidence among exposed (I_e) and non-exposed people (I_n). The formula $I_e - I_n$ can be rewritten as $RR(I_n) - I_n$, or as $I_n(RR - 1)$. Because the relative risk can be estimated from the results of a case–control study by means of the odds ratio, the only additional piece of information needed to estimate the attributable risk is an estimate of I_n . For the population in which the study has been conducted, I_n can be estimated if:

1. The overall incidence (I) of the disease in that population is known or can be approximated.
2. The frequency of exposure (P_e) in the controls selected for study reasonably reflects that of the population that gave rise to the cases.

Given (1) and (2):

$$\begin{aligned} I &= I_e(P_e) + I_n(1 - P_e) \\ &= I_n RR(P_e) + I_n(1 - P_e) \\ &= I_n[P_e(RR - 1) + 1] \end{aligned}$$

So:

$$I_n = \frac{I}{P_e(RR - 1) + 1}$$

Therefore:

$$AR = \frac{I(RR - 1)}{P_e + (RR - 1)} = \frac{I}{P_e + 1 / (RR - 1)}.$$

For example, consider a disease with an incidence rate of 10 per 100,000 per year in a population in which 5 per cent of people have been exposed during a relevant period of time. Table 5.5.5 summarizes data from a case–control study conducted in that population.

The attributable risk that corresponds to the estimated 3.35-fold increase in risk is

$$\frac{10}{0.05 + 1 / (3.35 - 1)} = 21.0 \text{ per } 100\,000 \text{ per year.}$$

Table 5.5.5 Depiction of results from a hypothetical case–control study involving a dichotomous exposure variable

Exposed	Cases (%)	Controls (%)	OR
Yes	15	5	3.35
No	85	95	1

From the results of case–control studies that suggest a causal relation, it is also possible to estimate the percentage of exposed people with the disease who developed it because of their exposure, rather than through one or more causal pathways not involving the exposure. This measure, often termed the ‘attributable risk per cent’ (AR per cent) among exposed people, is defined as

$$\frac{I_e - I_n}{I_e} \times 100.$$

It can be described in terms of the relative risk alone:

$$AR\% = \frac{I_e}{I_e} - \frac{I_n}{I_e} = 1 - \frac{1}{RR} = \frac{RR - 1}{RR} \times 100.$$

Therefore, the results of a case–control study that provide a valid estimate of the relative risk (via the odds ratio) can provide the attributable risk per cent as well, with no additional assumptions or sources of data. It is also possible to estimate the percentage of a disease’s occurrence in the population as a whole that resulted from the actions of given exposure. This measure, the ‘population attributable risk per cent’ (PAR per cent) or ‘aetiological fraction’, is simply the attributable risk per cent multiplied by the proportion of cases in that population who were exposed (P_e):

$$PAR\% = AR\%P_e.$$

In the present example:

$$AR\% = \frac{3.35 - 1}{3.35} = 70.1\%$$

and

$$PAR\% = 70.1\% (0.15) = 10.5\%.$$

The role of case–control studies in understanding disease aetiology

Randomized trials will not be able to answer all questions regarding the reasons for disease occurrence. Many potential disease-causing or disease-preventing exposures cannot be manipulated, either at all—for example, most genetic characteristics—or in any practical way for purposes of a study. For many exposure–disease relationships, either the disease is too uncommon or the induction period is too long to conduct a randomized trial that is not unfeasibly large in size or long in duration. Finally,

it generally will not be possible to conduct separate randomized trials to measure the impact of all potential types, amounts, and durations of a class of exposure.

Also, it is not possible to rely solely on cohort studies for answers. Just as with randomized trials, the disease outcome being studied may be too rare to allow a cohort approach to be useful. This explains why the aetiologies of vaginal adenocarcinoma and Reye's syndrome, for example, have been evaluated exclusively by case-control studies—these diseases are simply too uncommon for most cohort studies to generate any cases, even in 'exposed' individuals. Prospective cohort studies are also of limited use when the induction period for the exposure-disease relationship is either very short or very long. If the induction period is very short and the exposure status of an individual varies over time, a cohort study would need to assess exposure status repeatedly among cohort members. For this reason, studies of alcohol consumption and the occurrence of injuries typically are case-control in nature (Holcomb 1938). Similarly, unless information on exposure status can be ascertained retrospectively, it would not be feasible to initiate a cohort study of a suspected aetiological relation that requires a very long time (perhaps several decades) to manifest itself.

Although case-control studies may be of particular value in the evaluation of the aetiology of uncommon disease, they may have difficulty in obtaining statistically precise results if the frequency of the exposure in the population under study is either extremely common or extremely uncommon (Crombie 1981). Thus, only an association as strong as the one between cigarette smoking and lung cancer could have emerged reliably from case-control studies of several hundred British men conducted in the late 1940s (Doll and Hill 1950), given that well over 90 per cent of that population were cigarette smokers. For very uncommon exposures—for example, occupational exposure to a specific substance suspected of posing a risk to health, or an infrequently prescribed drug—barring a strong observed association based on a large number of subjects, even the best-designed case-control study will usually offer no more than a suggestion of the presence or absence of a relation with regard to the occurrence of a given illness.

Conclusion

- ♦ Case-control studies compare ill or injured persons (cases) with those at risk of the illness or injury (controls) in terms of prior exposures or characteristics.
- ♦ From most case-control studies of a given condition it is possible to obtain an estimate of the relative risk associated with an exposure by dividing the odds of exposure in cases by the odds of exposure in controls (odds ratio).
- ♦ The validity of the results of a case-control study can be compromised by differences between cases and controls with regard to exposures or characteristics that are also correlated with the likelihood or degree of the exposure in question.
- ♦ In most case-control studies, ascertainment of exposure status is undertaken after the cases have sustained their illness or injury. These studies will produce an unbiased estimate of an exposure-disease association to the extent that exposure status prior to disease onset can be ascertained with a high degree of sensitivity and specificity.

- ♦ In a setting in which (1) randomization of potential study participants is unethical or infeasible and (2) the outcome under study is an uncommon one, data from case-control studies may be the best available by which to judge a potential cause-effect relationship between the exposure and outcome.

Cohort studies

Alvaro Muñoz and F. Javier Nieto

Introduction to cohort studies

Cohort studies constitute one of the basic types of designs in epidemiological research. The key element of cohort studies is temporality (i.e. exposure preceding an outcome). Specifically, a cohort (i.e. group of individuals) is enrolled at the beginning of the study (baseline) to examine how characteristics (exposures) predict the occurrence of a discrete event (typically a disease onset) or changes in markers of health/disease status. In the former case, the cohort is typically formed by individuals who are free from the outcome of interest and have sufficiently heterogeneous profiles of putative risk factors (whose simplest form is as exposed or unexposed). In the latter case, the central aim is to characterize the heterogeneity of the change or trajectory of markers of disease progression according to constellations of putative risk factors.

The identification of exposures and risk factors for disease provides a basis for prevention. There are numerous examples of cohort-based exposure–disease associations that have resulted in beneficial prevention strategies: for instance, to prevent lung cancer, cigarette smoking should be avoided; to prevent infection with human immunodeficiency virus (HIV), high-risk sexual practices and injection with unsterile needles should be avoided; to prevent the development of acquired immune deficiency syndrome (AIDS) and death among individuals infected with HIV, antiretroviral therapy should be taken to suppress viral replication; to prevent heart disease, low levels of high-density and high levels of low-density lipids should be avoided (by diet, exercise, and/or lipid-lowering medications); to prevent cervical cancer, infection with human papilloma virus (HPV) should be avoided. Needless to say, there are instances in which the design of prevention strategies faces the complexity of multifactorial aetiology and of exposures that cluster so that exposures have to be taken into account jointly, and the lack of such recognition may lead to ascribing to a particular exposure an effect that is not appropriate. When an exposure is not a *sufficient* cause but a *component* of a more complex constellation of causal factors (Rothman et al. 2008; Szklo and Nieto 2012), acting only on that exposure may not result in successful prevention strategies; for example, based on data from cohort studies, high levels of beta-carotene markers (purportedly resulting from appropriate diets) have been associated with protection against cancer (Willett et al. 1984), but supplementation with beta carotene only has not resulted in a lower incidence of cancer in clinical trials (ATBC Cancer Prevention Study Group 1994; Virtamo et al. 2003).

Types of cohort studies

The observational cohort design shares with the experimental design or controlled clinical trial the temporal relationship between exposure and disease, of the putative cause with the supposed effect. The clinical trial design is a special type of cohort study in which the study subjects are randomly assigned to the different experimental (exposure) groups. Given the inherent limitation of observational designs to control for potential confounding variables unidentified by the investigator, the difference between these study designs lies on the validity of the conclusions regarding the potential causal relationships between exposure and disease. The role of randomization in clinical trials is to make the two groups comparable so that the effect of the therapy can be determined. But randomized controlled trials are not ethical or feasible when exploring the effects of potentially harmful exposures; moreover, the generalizability of results in highly selected trial participants is often limited. This is the reason why observational cohort studies, with all their limitations and caveats, will always be an important study design in epidemiological research.

In some studies, the investigator collects the data *concurrently* with the study being conducted, and in others, the data are available before the study is designed and the study is conducted to obtain that data (i.e. the data for the study precedes its conduct or the study is *non-concurrent*). This type of design is called ‘retrospective study’ by some authors (Kelsey et al. 1986; Vandembroucke 1991), a term that can cause confusion because, as mentioned, it is also used for case–control studies. It is possible that studies collect data concurrently for some participants and non-concurrently (*historically*) for the remainder of the study population.

The simplest cohort design is to obtain exposure data at baseline and follow up individuals to only obtain data for when the event of interest occurs. A richer design includes regularly scheduled visits at which data on exposures are updated, and in many cases, biological samples are collected for testing to assess those exposures. Cohort studies with regularly scheduled visits for updating exposure information and/or determining outcomes are referred to as *panel studies* (Kelsey et al. 1986). When the outcome of interest is not an event but it is changes in the profile of a biomarker over time (e.g. change in kidney function measured by filtration rate), panel studies are often referred to as *longitudinal studies*.

Design issues in cohort studies

The nature of a cohort study provides the temporal structure necessary to associate a particular exposure with a subsequent

event of interest. Documentation of the time sequences of exposures and events generates data upon which the course of event development can be modelled. Such data provide flexibility to define the study outcome based on the length of time elapsed between exposure and event. The time at which an exposure first occurs, placing individuals at risk for event development, is referred to as the *origin* (e.g. birth in population-level life-course epidemiology, infection with a virus or bacteria in infectious disease epidemiology). Ideally, a cohort study will have complete data of the time elapsed between the origin and the event of interest for as many participants as possible. However, in most studies, not all individuals are followed up from the origin: some will have been at risk for some time since the origin when enrolled into the cohort study. Those followed up from the origin are called the *incident* cohort and those entering the study after a certain duration from the origin are called the *prevalent* cohort. Implementation of the appropriate statistical methods to combine incident and prevalent cohorts may not only yield more efficient estimates but also provide the means for appropriately describing the timing of events beyond the study duration (Muñoz et al. 1997).

For some diseases, the origin is well defined and observable, such as employment into an occupation deemed to place workers at risk for health events. For others, the origin is well defined but difficult to observe, such as infection with a virus (e.g. sexual transmission of HPV, whose occurrence can be determined in a cohort study by following uninfected sexually active individuals with regularly scheduled visits at which the participants are tested for presence of antibodies to HPV). Still others do not have a well-defined origin, as in the case of coronary heart disease in which the origin may be the time of initiation of atherosclerotic plaques in the inner layer of the coronary arteries, the time when a certain level of coronary artery stenosis is reached, or the time when an atherosclerotic plaque ruptures and acutely occludes an arterial branch leading to clinical manifestations (angina or myocardial infarction). Cohort studies with data on individuals from origin to the event of interest as well as with baseline information and updated information on predictors at regular intervals between the origin and event provide the most complete data to describe the natural history of a disease (Muñoz et al. 1992; Muñoz and Xu 1996; Muñoz et al. 1997).

Study population

In a cohort design, the study population comprises individuals who are exposed or unexposed to the suspected risk factors and who are at risk for the disease of interest. Once the study population has been deemed to be free of the event whose occurrence is to be documented during the proposed follow-up, it should be ensured that the participants have enough variability in the presence and/or magnitude of exposure to the risk factor or factors of interest.

The cohort can be the totality (or almost the totality) of a geographically and temporally defined population. For example, Hoffmans et al. (1988) constructed a non-concurrent study of mortality among Dutch males born in 1932. This cohort included the totality of the 84,349 Dutch males who were 18 years old in 1950, when they were examined for eligibility to military service; the investigators used the data collected at baseline (when the individuals were 18 years old) to describe the relationship

between obesity at 18 years and subsequent cause-specific mortality (Hoffmans et al. 1989).

Instead of the totality of a population, it is more common to include only a fraction or a sample of a population defined temporally and geographically. For instance, as outlined in Table 5.6.1, the Framingham study was initiated at the beginning of the 1950s in Framingham, Massachusetts, United States, with the goal of studying the incidence of and risk factors for cardiovascular diseases (Dawber 1980). From a list of residents aged 35–59 years (18,000 persons in total), 6507 adults were randomly selected, among whom 4469 agreed to participate in the initial examination. In order to compensate for the unexpectedly high rate of refusal, the investigators decided to include 734 individuals who, although not part of the random sample, had expressed interest in being part of the cohort. Of the resulting 5203 participants in the baseline examination, 76 persons were excluded for having clinical manifestations of cardiovascular disease, leaving a total of 5127 participants in the Framingham Heart Study cohort. The follow-up consisted of physical examinations every 2 years with comprehensive data collection particularly emphasizing diet, physical activity, and stress.

The generalization of results obtained from a cohort study whose participants are a sample from a sole population may have serious limitations, which are overcome by other studies that enrol participants from diverse populations. Indeed, the tradition initiated by the Framingham cohort study was complemented by three large cohort studies of cardiovascular disease conducted in the 1980s, which covered practically the whole spectrum of adults (≥ 18 years) as well as diverse ethnic and socioeconomic groups in the United States. Specifically, the CARDIA study (Friedman et al. 1988) recruited a total of 5115 persons between 18 and 30 years of age in four states; the ARIC study (ARIC Investigators 1989) cohort comprised 15,800 persons aged 45–64 years at the beginning of the study and residents of four states; and the CHS (Fried et al. 1991) followed up 2955 participants 65 years or older in another four communities of the United States.

In addition to strict temporal and geographic criteria, a cohort can also be defined by a group of individuals sharing common characteristics, which facilitates the follow-up and/or the accuracy and precision of the data to be collected. For example, the Multicenter AIDS Cohort Study (MACS) (Kaslow et al. 1987; Dudley et al. 1995) comprised homosexual men in four metropolitan areas of the United States with the overall aim of describing the natural history of HIV infection and AIDS (see Table 5.6.1), from the risk factors of infection with HIV to the hazard of death among those developing AIDS.

From April 1984 to March 1985, a cohort of 4954 men was recruited into the MACS in four metropolitan areas of the United States (Baltimore, Chicago, Los Angeles, and Pittsburgh). To increase minority enrolment, an additional 668 men, 69.3 per cent of whom were non-Caucasian, were recruited in 1987–1991. To address issues of long-term effectiveness of therapies and their putative adverse effects, 1350 men were additionally enrolled in 2001–2003. In 2010, an additional 47 men were recruited in Baltimore and Pittsburgh. Therefore, the entire MACS cohort as of September 2012 consisted of 7019 men with three primary inclusion criteria: men having sex with men, older than 18 years, and AIDS-free. Of them, 2905 (41 per cent) were seroprevalent for HIV at entry into the study. All men were followed up every 6 months

Table 5.6.1 Examples of cohort studies

	Framingham (Dawber 1980)	MACS (Kaslow et al. 1987; Dudley et al. 1995)	Norwegian electricians (Tynes et al. 1992)
Study aims	Incidence and risk factors for cardiovascular diseases and hypertension	Natural history of HIV infection and AIDS	Relationship between electromagnetic radiation and cancer incidence
Type of study	Concurrent	Concurrent	Non-concurrent
Date	1949–present	1984–present	1960–1991
Study population	Adults resident in Framingham, Massachusetts, USA	Homosexual men in four metropolitan areas of the USA	Electricians in 1960 census in Norway
Sample size	5127	7019	37,945
Sex	Male and female	Male	Male
Age at baseline (years)	30–62	18–70	20–70
Active follow-up	Study visits every 2 years including physical exam, electrocardiogram, and laboratory exams	Study visits every 6 months with extensive interviews including behaviour and medical care, physical exam, laboratory exams and collection of blood samples for national repository.	Not applicable
Passive follow-up	Clinical records (in case of hospitalization) Death certificates	Clinical records Death certificates National Death Index	Cancer registries Death certificates

Source: data from Dawber (1980), Kaslow et al. (1987), Dudley et al. (1995), and Tynes et al. (1992).

with repeat interviews, physical examinations, and collection of blood. Serological tests for HIV antibody were routinely carried out at each visit. Up to September 2012, the dates of last negative and first positive visits (i.e. seroconverters) were known for 704 men. Using blood samples collected at each semi-annual visit in order to characterize the level of HIV-induced immunosuppression, mononuclear cells were analysed by two-colour flow cytometry with antibodies specific for CD3, CD4, and CD8. Confirmation of AIDS diagnoses was made by obtaining physician and hospital summaries and by reviewing medical records; 1976 AIDS cases were observed up to September 2012. Deaths were monitored by follow-up and through an ongoing search of death records. A total of 2136 participants died before September 2012.

When a specific registry with baseline data is available, it provides the opportunity to conduct a non-concurrent cohort study. For example, Nieto et al. (1992) used a registry of physical examinations carried out on schoolchildren between 1933 and 1945 in Hagerstown (Maryland, United States) to assemble a non-concurrent cohort of about 13,000 children in order to study the relationship between childhood obesity and adult mortality; the baseline information obtained between 1933 and 1945 was linked to the mortality experience of the cohort up to 1985. In other historical cohorts, the study population is defined from the beginning as a function of the exposure factors to be investigated. Thus, participants are selected explicitly according to the presence or absence of the characteristics considered to be possible risk factors, such as a cohort of Norwegian electricians. As summarized in Table 5.6.1, this historical cohort of 37,945 workers was defined from the registry of occupations of the working population in Norway according to the 1960 census (Tynes et al. 1992).

With the increasing availability of electronic health records, new opportunities to use administrative healthcare databases

as a basis for defining and conducting large-scale cohort studies are emerging (Phillips et al. 1999; Lau et al. 2007; Sterne et al. 2009; Manolio et al. 2012). These approaches offer the opportunity to carry out studies in large samples of tens or hundreds of thousands of individuals at relatively limited costs. They can be particularly powerful when combined with a comprehensive system of national registries, such as those offered by countries like Denmark (Frank 2000). These approaches may be limited, however, by the relative scarcity of ‘negative’ controls (i.e. healthy subjects) and by an under-representation of people who do not have access to (or choose not to take advantage of) healthcare services. In addition, the quality of the data collected for clinical purposes is variable, not usually subject to the rigours of standardization and quality typical in research settings, especially when studying phenomena that are not directly related to clinical care (e.g. upstream community determinants, psychosocial factors).

Finally, cohort studies can outlive themselves such as when the offspring of the cohort members are recruited into a so-called ‘offspring’ cohort, often with the purpose of conducting family and genetic studies. The Framingham Heart Study was again a pioneer in this methodology, when in the late 1970s the daughters and sons of the original cohort members (and their spouses) were recruited to constitute the Framingham Offspring Study (Kannel et al. 1979; Djoussé et al. 2002). Another example is the Beaver Dam Offspring Study, which recruited adult children (21 years or older) of the participants in the Epidemiology of Hearing Loss Study, a population sample based in the town of Beaver Dam, Wisconsin, United States (Cruickshanks et al. 2009).

Baseline visit

The objective of the baseline visit in a concurrent cohort study is generally the classification of the study participants according

to the exposure factor or factors under investigation, as well as according to potentially relevant covariates (confounders) and/or effect modifiers. For example, Furth et al. (2006 and 2011) designed a cohort of children with chronic kidney disease to determine the risk factors for progression towards end-stage renal disease; for this, they recruited 586 children aged 1–16 years with an estimated glomerular filtration rate of between 30 and 90 mL/min/1.73 m², indicating a level of insufficiency in their kidney function that put them at risk of end-stage renal disease. Also important is the collection of information that facilitates the subsequent tracking of study participants during the follow-up including information on contacts.

In its simplest form, the baseline visit can take place over a single continuous time period until the desired sample size is reached. In many cases, however, more participants are recruited: (1) to replace those who have developed the event of interest or who have been lost to follow-up, (2) to include groups of individuals who were under-represented in the original recruitment, and/or (3) to respond to new scientific challenges due to the changing nature of the epidemiology of the disease of interest

Follow-up

The follow-up can be active, by repeated contacts via successive visits to a health centre, mailed questionnaires, or phone calls. Sometimes, the different forms of contacting participants are alternated. For example, in the follow-up of the ARIC study, participants were invited every 3 years to return to the clinic for a new physical examination and complementary assessments (ARIC Investigators 1989); in addition, each participant was called every year and asked about illnesses and hospitalizations occurring in the interim period since the last clinic visit. In the MACS, the visits are scheduled every 6 months and take place in dedicated settings instead of in a clinic. This is in contrast to clinic cohort studies in which visits take place according to the health needs of the participants.

For certain diseases and events (e.g. death, cancer), external sources (i.e. national death index, registries) can be used to record events occurring among the individuals enrolled in the study. The type and automation of the record linkage system is determined in each case by the availability of data and the characteristics of each particular registry (Oshima et al. 1979; Hole et al. 1981; Smith and Newcombe 1982; Newcombe 1984).

The quality of the information about the occurrence of events is fundamental for correct estimation of the incidence and its determinants. Therefore, in many cohort studies, a special effort is made to ensure that the information about disease occurrence or death is accurate. Generally, events recorded in interviews with study participants are verified by requesting documents such as the clinical records or death certificate of the subject, not only to verify the occurrence of the event but also to improve the information regarding diagnosis (e.g. to obtain the histological type in a study of lung cancer; to distinguish between thrombotic and haemorrhagic episodes in a study of cerebrovascular events). A major challenge in cohort studies with cause-specific mortality as the event of interest is the determination of the cause of death, which may require confirmation by inspecting clinical records or by interviewing the physician who attended to the participant before his or her death.

Types and measures of exposures

The classification of study participants according to exposure factors is one of the most complex challenges in a cohort study. *Exposure factor* means any attribute of the subject or any external agent that can influence his or her health (Armstrong et al. 1992).

Types of exposures

Exposure factors include host factors (such as age, sex, race, genetic factors, metabolic factors, and immune function) and environmental factors (such as viruses and bacteria, environmental pollutants, diet, alcohol, and/or tobacco consumption). Sometimes, an exposure factor represents a set of factors that are difficult to separate. For example, social class encompasses external environmental factors, related to individual behaviour, access to healthcare services, socioeconomic status, and others.

The exposures can be either fixed over time (e.g. sex) or variable. The latter could be exposures that change directly with time (e.g. age and calendar) or change at their own pace with time (e.g. cigarettes smoked per day, biological marker levels, diet). When exposures not only change over time but do so heterogeneously (i.e. change differently over time in different individuals), they are referred to as *internal* (i.e. at the individual level) time-dependent exposures. In contrast, exposures that change over time but affect groups or populations who are subject to the exposure in a similar way are referred to as *external* (i.e. at the population level) time-dependent exposures (i.e. they change equally over time for different individuals comprising a given population). The most common example of an external variable is calendar time, which is the same for the whole population. Other examples of external time-dependent exposures include the following: seasonal weather changes, levels of air pollution in a given region, supplements in the food and water supply, and medical therapies/procedures used in different calendar periods.

Follow-up visits in the setting of a cohort study provide the opportunity for collecting data to update internal time-dependent exposures. External time-dependent exposures may be obtained from external sources, but data obtained at the individual level can sometimes be used to define eras (i.e. calendar periods) when there are changes at the population level. For example, the MACS started in 1984 and has since been conducted concurrently with major advances in therapies effective against viral replication in HIV-infected individuals. In 1998, Detels et al. determined the effectiveness of the potent antiretroviral therapies introduced in 1995 by showing a doubling of the AIDS-free times under the conditions of the first two years (July 1995–July 1997) of the highly active antiretroviral therapy (HAART) era (Detels et al. 1998). In 2005, Schneider et al. determined the population effectiveness of prolonged use of HAART by showing that in the era when HAART was well established (i.e. July 2001–December 2005, 6–10 years after its introduction in July 1995), the median survival time after AIDS diagnosis increased tenfold from the 1.5 years in the era when no therapies were available (Schneider et al. 2005).

In cohort studies, two types of effects of interventions can be measured. The first can be termed ‘individual effectiveness’, which mimics clinical trials by using treatment data at the individual level. These analyses must overcome the lack of randomization and the confounding by indication, whereby those individuals at more advanced disease stages are the ones more likely to receive

the therapies (Ahdieh et al. 2000). Measures of individual effectiveness *supplement* (and typically support and extend) the results of clinical trials, but are usually subject to an unknown amount of residual confounding (Phillips et al. 1999). Data-analysis methods for individual effectiveness require the use of multivariate methods of survival analysis, including the use of therapy as an internal time-dependent covariate; however, the complexity of the selection of individuals receiving therapies may require the use of more elaborate methods for causal inferences (Robins et al. 2000; Cole et al. 2003). Randomized clinical trials are typically considered a standard study design for inference of the causal effect of an exposure on an outcome. However, when the exposure is predicted to be detrimental to health (e.g. abnormal birth history), an observational study design is a suitable choice to investigate the effect of the exposure on an outcome. Established methods are available to attempt to mimic randomized experiments for the purpose of estimating causal effects in observational studies. These approaches include propensity score matching methods (Stuart 2010), inverse probability weights based on propensity scores (Robins et al. 2000), and marginal structural models (Hernán et al. 2001). The guiding principle of these approaches is to construct a sample in which two or more groups (e.g. exposed/unexposed) have identical (or balanced) distributions of confounders (Stuart 2010).

There is growing interest in determining the effectiveness of the many therapies participants in cohort studies are observed to receive but there is strong confounding by indication as therapies tend to be given to individuals who fulfil guidelines for who and when to treat. Standard regression adjustments to compare outcomes of treated to those untreated seldom achieve control for the indication for receiving treatment. Alternative approaches include the use of inverse probability weights based on probability of receiving treatment. Inverse probability weights estimators provide an excellent means for estimating the causal effects of treatment among individuals with different covariate values at study baseline (Robins et al. 2000). However, covariates are often dynamic and changing values may alter the impact of therapy on the outcome. Further, marginal structural models are limited in their flexibility, becoming unstable if certain covariate values yield very large or very small probabilities of treatment. Inverse probability weights methods offer powerful tools to deal with complex patterns of confounding, particularly in longitudinal data, where outcomes at one time point may influence both subsequent treatments and outcomes. More elaborate methods such as marginal structural models have been proposed to deal with these types of patterns, whereby the weights in these models are updated longitudinally using the complete past history. In addition, the weights are stabilized, resulting in improved performance. Many scientific initiatives present research questions involving strong confounders for which these approaches may overcome the limitations of classical multivariate regression methods. Although these methods offer great potential (e.g. Kitahata et al. 2009), their implementation could be problematic as it requires complex procedures and clear understanding of the required steps and algorithms to properly mimic a clinical trial in the setting of observational data (Hernán and Robins 2009). Furthermore, the attempts to analyse observational studies like randomized experiments (Hernán et al. 2008) can be controversial (Stampfer 2008; Willet et al. 2008) but may result in improvements of methods to compare groups and to characterize when a given exposure (e.g. years after menopause

when hormone replacement therapy is initiated) may exert an effect on a health outcome (Hoover 2008; Prentice 2008).

The second type of effect that can be measured in a cohort study can be termed ‘population effectiveness’, which compares the occurrence of disease in the population when the most ill are treated to the occurrence of disease in the population when none or only few are treated with a given therapy. Because the introduction and use of therapies are closely linked to calendar time, the primary comparison may be characterized by time periods. When periods are characterized by differential availability of therapies, they could then play the role of an *instrumental variable* (related to therapy but not to disease progression or markers indicative of therapy need) and thus provide an accurate effect of the benefits of therapy at the population level (Greenland 2000; Martens et al. 2006). To control for survival bias and overall disease progression, this approach requires the comparison of groups reaching similar time at risk (e.g. duration of infection or time since disease diagnosis) in different eras of therapy defined by calendar periods (Hoover et al. 1994; Muñoz and Hoover 1995; Detels et al. 1998; Schneider et al. 2005). Measures of population effectiveness *complement* the efficacy measured in clinical trials and provide a key public health index: the amount of disease burden that is reduced when only some (typically the most ill) receive the therapy of interest (Muñoz et al. 2000). Comprehensive data collected by cohort studies are essential to eliminate possible ecological fallaciousness (i.e. effectiveness due to changes over time other than changes in the therapies of interest). This includes not only prospectively collected data on therapy use, but also information on access, healthcare utilization and practices, and adherence at the population level.

Measures of exposures

The exposure can be defined as a quantitative (continuous) variable (e.g. blood pressure) or qualitative (categorical) variable (e.g. non-smoker, ex-smoker, current smoker).

When exposures are assessed repeatedly over time, the investigators can take into account not only the amount (dose) but also the duration of the exposure (Armstrong et al. 1992). There are several ways of quantifying dose and duration: (1) cumulative exposure (e.g. number of pack-years of smoking, number of rad-years of exposure to a radioactive compound at work), (2) the average exposure during the latest years (e.g. average number of cigarettes per day, average number of rads in the work environment), or (3) maximum exposure (e.g. maximum number of cigarettes per day, maximum level of radioactivity registered in the industry).

The most typical data-collection instruments in epidemiological practice are questionnaires, physical examination, and registries. Questionnaires allow not only the obtaining of information on demographic data, personal and family history, disease symptoms, behaviours, and attitudes, but also the recording of self-reported physical characteristics such as weight and height. They can be administered through personal or telephone interviews, they can be completed by the participants themselves, or they can be administered by a computer-assisted method, which is particularly useful for the collection of sensitive data (e.g. sexual behaviour, drug abuse). Modern technologies are significantly expanding the range of possible modalities for data collection. Web-based instruments, smartphones, and other types of mobile

devices are being used to collect information on dietary habits and other types of exposures (Illner et al. 2012). In addition, registries are external sources that can be used to complement the active follow-up and are particularly useful to obtain vital status events or diagnosis of a condition of interest (e.g. cancer registries).

Timescales and types of outcomes

The scientific aims of a cohort study should dictate the type of outcome or measure of disease occurrence that should be collected during follow-up. The most common measure of disease in cohort studies is the time individuals at risk take to develop an end point. To properly describe this time, the following need to be defined: (1) the origin, which marks the time at which individuals are placed at risk for the development of the particular event of interest; (2) the end point, which typically is the onset of a clinical condition or the occurrence of death; and (3) the scale of time.

Types of timescales

Traditionally, the timescale used in cohort studies is the time from the beginning of the study (when the cohort is identified and the baseline exam is conducted) until the event of interest (or censoring, as discussed in the next subsection) occurs. For example, in many of the analyses of the Framingham Study data, the origin (time 0) of the follow-up is defined as the date when the baseline interview/exam of each of the participants took place in or at around 1950. The fact that individuals start at different ages is dealt with in the analysis by statistically *controlling* for baseline age.

Whether or not an origin is well defined, the use of *age* as the timescale is an appealing alternative (Korn et al. 1997). The caveat of this approach when applied to a cohort of individuals entering at different ages (e.g. in adulthood) is that individuals are not under observation during the years from birth to the age at which they are recruited into the cohort. This needs to be handled in the analysis allowing for late entry (left truncation—see following subsection). This method was used, for example, in a study of the relation between sleep apnoea and cancer mortality in the Wisconsin Sleep Cohort (Nieto et al. 2012). Another application of age as the timescale was the characterization by Wada et al. (2013, 2014) of life expectancies of HIV-infected individuals in the era of HAART.

In most cases, even for groups of individuals with a persistent (e.g. fixed) exposure, the pattern of incidence of disease over the follow-up time is not the same at different durations at risk. An exposure whose deleterious effect monotonically accumulates over time will result in an incidence rate that increases with time (e.g. death after AIDS diagnosis in the absence of treatment). An exposure that first affects susceptible individuals so that those remaining free of the event over time represent resistance (i.e. some degree of immunity to the effects of exposure) will result in an increasing incidence followed by a decreasing incidence rate (e.g. a viral infection to which a subset of individuals are immune). An exposure that initially carries risk that ameliorates over time will result in a decreasing incidence rate (e.g. death after transplantation). A beneficial intervention that decreases the risk of death but whose effect is obliterated by other processes including old age will result in a bathtub hazard (Cox et al. 2013).

Incomplete observation from the origin and to the event

In some cohort studies, not all individuals are observed from the origin, but some enter the study after having been at risk for varying lengths of time. This type of incompleteness in the data is referred to as *late entries* or *staggered entries* and occurs when some individuals have experienced the origin that places them at risk for the event of interest at a date prior to their enrolment into a cohort study. Since these individuals have survived free of the event of interest from the origin to study enrolment, they have peers with similar origins who did not survive event-free and developed the event of interest prior to the cohort study enrolment, precluding their participation in the study. Such unseen individuals are *truncated*, and methods to adjust for these truncated observations need to be implemented by appropriately handling late entries. The presence of late entries in a study is a case of missing data, where missing data are the number and timing of the events of the truncated peers of those who entered late. Indeed, if an individual enters a cohort study w years after his/her time of origin, there are $[1 - S(w)] / S(w)$ truncated individuals who have not been included in the study. This is because the cohort would have needed to enrol a total of $1 / S(w)$ individuals for one of them to survive event-free for w years and be enrolled in the study.

With respect to the event, observations in a cohort study are incomplete because it is unfeasible for the investigator to observe the event in all participating individuals. This type of incompleteness in the data is called *censoring* and can be due to any of the following: individuals being observed as event-free on the date of analysis, sometimes called *administrative censoring*; individuals being lost to follow-up (prior to the date of analysis) before developing the event; or deaths due to unrelated causes, precluding the observation of the event of interest.

When the follow-up is ended by the investigators (e.g. because the source of funding for the study is exhausted), the participants still under follow-up without having experienced the event of interest are considered administrative losses. When participants emigrate during the course of the follow-up, change addresses or telephone numbers making them untraceable, or refuse to continue participating, they are considered censored observations due to follow-up losses. When death is the reason for censoring an event of interest, it is more appropriate to use methods of analysis based on competing risk models (Putter et al. 2007), which consider the deaths as exits or removals from the risk set as opposed to treating the deaths as observations that could have been observed had the participants not died before the event of interest occurred (Fine and Gray 1999; Checkley et al. 2010).

For the most part, subjects who are lost to follow-up are *right-censored*, which means that their exit from observation is the last possible time they contributed information to the study (i.e. on the timeline of their participation represented by a scale running from left to right, no data are available to the right of the time of censoring). Occasionally, information from sources external to the study (e.g. death certificates) are used to identify the interval of time during which individuals lost to follow-up and free of the event of interest are documented to have had the event because they died of the event of interest at some time point after the censoring. This interval is defined as the time between the date the individual was lost to follow-up and the date of death. Given

that the individual died of the event of interest, the event must have occurred during this interval. These observations are called *interval-censored* observations. When using age as the timescale with mortality as the end point, censored observations are all interval censored as all individuals are expected to die by age 100 (Wada et al. 2013, 2014).

In the survival analysis section, we will discuss the issues regarding the relationships between the censoring mechanisms and the disease process, as well as the need for properly incorporating not only censoring (i.e. incomplete data on events) but also truncation resulting from late entries (i.e. incomplete data on origins) into the data analysis.

Time-to-event

The nature of a cohort study provides the temporal structure necessary to associate a particular exposure with a subsequent event of interest. Documentation of the time sequences of exposures and events generates data upon which the course of event development can be modelled. The use of time-to-event outcomes requires that the *time* variable be anchored at the origin, resulting in the characterization of the event incidence across the time since origin. In other words, the incidence of the event from 5 to 7 years past the origin will be handled differently in the analysis than the incidence from 9 to 11 years, even though both time periods equally span 2 person-years.

Examples of time-to-event outcomes used in epidemiological research include the following: (1) in clinical epidemiology, the classic time from diagnosis of a clinical condition to death or the time from initiating therapy to response; (2) in infectious disease epidemiology, the time from infection to overt disease (i.e. the incubation period); (3) in cancer epidemiology, the time from remission to relapse; (4) in behavioural epidemiology, the time from enrolment into a smoking cessation programme to the time the individual quits smoking; and (5) in occupational epidemiology, the time from employment to the occurrence of an occupationally related health outcome.

Change of biomarkers

In some cohort studies, the primary event is not an event but whether a marker of disease changes over time differently in individuals exposed to different risk factors. For example, in the cohort study of children with moderate kidney function insufficiency conducted by Furth et al. (2006), the primary objective was to identify the factors that predicted fast decline of kidney function (Pierce et al. 2011). Another example is the cohort study conducted

by Tager et al. (1983) in East Boston in the 1970s, showing the effect of maternal smoking on slowing the expected increase of pulmonary function in growing children. The study was seminal to the subsequent mounting evidence that second-hand (involuntary) smoking had detrimental health effects and guided the issuing of policies to ban smoking from work and public places as fundamental prevention measures for the health of the public. Furthermore, cohort studies have not only contributed substantially to the elucidation of disease aetiology but have also spurred the development of statistical methods to properly analyse data. For example, Rosner et al. (1985) developed methods for the analyses of data presented in their work in collaboration with Tager et al. (1983).

Analysis

A fundamental condition for valid epidemiological inferences is that for the disease to be (causally) linked to a given exposure, the exposed and unexposed groups should be comparable with respect to factors that are known to explain the heterogeneity of disease occurrence (i.e. no confounding). In cohort (observational) studies, comparability needs to be achieved by the use of appropriate analytical methods which often require approaches above and beyond classical stratification and/or regression methods. The goal of causal inference methods is to try to mimic randomization so as to assess the effect of a given exposure in groups of individuals who differ in the exposure of interest, but who are otherwise comparable with respect to all variables known to be associated with disease.

The type of outcome of interest determines the type of analytical technique most appropriate to yield a valid inference. Table 5.6.2 provides a succinct summary of the analytical methods reviewed here.

When the outcome data are collected as events in person-years, Poisson regression methods are apt for data analysis (outcome I in Table 5.6.2). These methods are particularly useful for the analysis of trends and changes in incidence of disease over calendar time; they are of great utility for data in which an origin is not well defined or not of interest, which will be the case if the rate of disease occurrence is assumed to be constant within a defined interval or period.

When the outcome data are times to event from a well-defined origin (outcome II in Table 5.6.2), the percentage of individuals remaining free of the event of interest at t units of time after the origin can be estimated by the Kaplan–Meier (Kaplan and

Table 5.6.2 Main methods for the analysis of cohort studies

Outcome	Summary measure	Comparison		Measure of association
		Exposed/unexposed (2-sample)	Multiple (regression)	
I Events in person-years	Incidence rate	(O-E) ² /variance	Poisson	Relative incidence
II Time to event	Kaplan–Meier/maximum likelihood estimates	Logrank or Mantel–Haenszel/likelihood ratio test	Proportional hazards/parametric	Relative hazard/relative time
III Biomarker repeatedly measured at follow-up visits	Change	t-test for simple measures of change between baseline and last visit	Regression for correlated data; marginal, conditional, random effects	Differences in change over time

Meier, 1958) curve or by maximum-likelihood methods for the non-parametric and parametric (Cox et al. 2007) approaches, respectively. Two survival curves can be compared using the Mantel–Haenszel (Mantel and Haenszel, 1959) test or the likelihood ratio test (Cox et al. 2007). Regression analysis can be accomplished under the semi-parametric assumption of proportional hazards (Cox, 1972) or under richer parametric models (Cox et al. 2007) which lend themselves more directly to estimation of relative times quantifying not only how the hazard is modified by an exposure but also to what extent an exposure shortens (if deleterious) or extends (if beneficial) the event-free times. Software in several statistical packages to incorporate not only censoring but late entries is widely available (Cox et al. 2007).

When the outcome is a biomarker repeatedly measured at follow-up visits (outcome III in Table 5.6.2), regression methods for correlated data need to be used. This is so because the biomarkers measured in the same individual over the follow-up visits are correlated so that the standard methods of regression methods for statistically independent outcomes are inadequate.

Analysis based on person-time

Calculation of person-time and rates

The methods described in this subsection are useful for the analysis of the frequency of events in person-years in groups of individuals with different exposures and when anchoring at the origin is not important. The primary aim is to describe the heterogeneity of the incidence in subgroups of the population defined by exposures, often including age and calendar.

To illustrate the methods, we present data from the Precursors Cohort study. This cohort comprised 1337 medical students of the

Johns Hopkins University, Baltimore, United States, who graduated between 1948 and 1964 (Klag et al. 1993). A total of 1271 students (95 per cent) completed a questionnaire and were examined during their stay at the school. In order to study the determining factors (‘precursors’) of general mortality and the occurrence of cardiovascular diseases, this cohort was followed up through mailed questionnaires. When the participants reported that they have had a myocardial infarction or another cardiovascular event, the hospital records were requested in order to validate the diagnosis. The vital status of the participants who did not respond was systematically investigated through calls to relatives and friends and through matching with the National Death Index. Table 5.6.3 shows data obtained in the follow-up for each of the groups (smokers and non-smokers), the column named ‘person-years’ showing the totality of time units lived by the members of the cohort between the indicated years of age. Thus, for example, the non-smokers in the cohort lived a total of 862.5 years while being 20–24 years old and 1929.5 years while being 25–29 years of age.

Univariate analysis

Internal comparison

The comparison of exposed and unexposed within a cohort can be done through the calculation of the standardized mortality ratio (SMR). Using data from the Precursors study, the last column of Table 5.6.3 shows the deaths ‘expected’ in the smokers if they had had the rates of the non-smokers. For example, the number of deaths expected in smokers aged 45–49 years old would be $0.00155 \text{ (deaths/year)} \times 2182.5 \text{ (person-years)} = 3.4 \text{ deaths}$. The SMR is the ratio of total observed deaths to the total expected deaths in smokers (if the smokers had the same age-specific rates as the non-smokers), which in this case is $57/29.8 = 1.9$.

Table 5.6.3 Internal comparison of the rates based on person-years in the Precursors Study. Occurrence of mortality (all-cause) until 1989, as a function of cigarette consumption at the baseline examination

Age (years)	Non-smokers			Smokers			
	Deaths	Person-years	Rate	Deaths	Person-years	Rate	Expected deaths ^a
20–24	1	862.5	0.00116	1	886.5	0.00113	1.0
25–29	2	1929.5	0.00104	2	2195.5	0.00091	2.3

External comparison

In other situations, it can be of interest to compare the mortality in the study group with the mortality of the total population that is used as reference. In this case, it is necessary to obtain the expected number of deaths using population-level rates from demographic statistics. Thus, in the Precursors study, the observed mortality can be compared with the mortality of the population of white males in the United States, as shown in Table 5.6.4. The total number of observed deaths ($23 + 57 = 80$) divided by the total number of expected deaths based on the demographic statistics provides the SMR of the cohort in comparison with the general population, which in case of data from Table 5.6.4 is $80/148.1 = 0.54$. This result implies that the mortality is almost half of what would be expected if the cohort had the same rates as that of the general population.

Multivariable analysis

The aim of multivariable analysis is to identify the constellation of exposures that explain the variability of incidence of disease, allowing for random variation under a probability distribution model. The Poisson distribution provides a useful and reasonable model to carry out the multivariable analysis of incidence rates observed in cohort studies. Ideally, the final regression model from a multivariable analysis should have an appropriate goodness of fit and be optimally parsimonious (i.e. with most regression coefficients being statistically significant).

Table 5.6.4 External comparison of the rates based on person-years in the Precursors Study. All-cause mortality until 1989, observed and expected according to national rates in 1980

Age (years)	National mortality rate ^a	Study cohort		
		Deaths	Person-years	Expected deaths ^b

Survival analysis

Time-to-event outcomes are used to accomplish the following epidemiological objectives: estimate the percentage of individuals that survive (i.e. remain event-free) for differing lengths of time from the origin, compare the survival of exposed and unexposed groups, and characterize the possibly multifactorial nature explaining observed heterogeneities in survival of different subgroups of individuals using multivariable analysis and regression methods.

Descriptors of the distribution of times-to-event

If T denotes the variable of time from origin to event, the simplest descriptor of the distribution of T is the *survival function* at time t (where t is a positive number), which is denoted by $S(t)$ and corresponds to the cumulative probability that an individual in the baseline cohort survives beyond time t . The survival function starts with a value of one and monotonically decreases towards zero. Its complement from $1 - S(t)$ is the cumulative incidence that an individual in the baseline cohort has the event before or at time t . The p th percentile, which is denoted by $t(p)$, is the time by which p per cent develop the event of interest; that is, when $1 - p = S(t(p))$. A widely used descriptor of survival times is the median, which is simply the 50th percentile, or the time since origin by which half of the individuals develop the event of interest.

The *hazard function* at t , which is denoted by $h(t)$, corresponds to the proportion of individuals who develop the event in the next unit of time among those who survive event-free until time t . That is, $h(t)$ equals the rate of decline of S at t divided by $S(t)$. The rate of decline of S is the *density function*, which is denoted by $f(t)$ and fulfils the equation $f(t) = h(t)S(t)$. It is important to note that $h(t)$ is a conditional probability and refers only to the subset of the cohort that survives event-free by time t .

Fig. 5.6.1 depicts the 25th percentile and hazard at $t = 12$ years of a survival function. The 25th percentile is 6 years (i.e. $t(0.25) = 6$ years), because it corresponds to the time by which 25 per cent of the individuals develop the event (i.e. 75 per cent survive). The hazard at $t = 12$ years is 10 per cent and corresponds to the ratio of $0.04/0.40$, which is the value of the rate of decline of the survival function at $t = 12$ (i.e. the density $t = 12$) divided by the value of S at $t = 12$.

The accumulation of h from zero to t (i.e. the area under the curve described by h from zero to t) denoted by $H(t)$ is the ‘summation’ of all instantaneous hazards ($h(t)$) between zero and t . There is a close and useful relationship between the survival function and the cumulative hazard at t : $S(t) = \exp[-H(t)]$, or equivalently, $H(t) = -\log[S(t)]$. Therefore, the cumulative hazard does not equate to the cumulative incidence of events by time t because $-\log[S(t)]$ is not equal to $1 - S(t)$.

Estimation of the survival function

The presence of censored observations is a case of missing data, and the fundamental role of the assumption that censored observations are not a selected subgroup is that, at any time during the study, individuals who remain under observation *represent* those subjects who were censored beforehand. The observation of events beyond the time an individual is censored provides the data to estimate when the censored individual is expected to develop the event had she or he remained in the study. Furthermore, because the individuals who are observed to develop the event are

Fig. 5.6.1 Survival function, the 25th percentile ($t(0.25)$) and hazard at $t = 12$ years ($h(12)$).

representative of the observations censored before their time of event, estimates of the hazard functions based on the observed individuals are unbiased, and thus they represent the hazards that the censored individuals would have experienced had they remained under observation in the study. Indeed, this forms the basis of the Kaplan–Meier method (Kaplan and Meier 1958), based on the calculation of the survival probability through the product of one minus the instantaneous hazards. The standard error of the estimators of the Kaplan–Meier survival function can be obtained from methods proposed by Greenwood (1926).

Fig. 5.6.2 shows five Kaplan–Meier curves according to the number of copies of HIV detected in 500 mL of plasma measured by branched-DNA (bDNA) in HIV-infected individuals followed up in the MACS cohort (Mellors et al. 1997). It clearly shows the great predictive value that viral load has for the development of AIDS. Indeed, investigators in the MACS have developed methods to quantify the variability of time to AIDS explained by viral load and have shown that it alone explained approximately 50 per cent of the variability of time to AIDS (Mellors et al. 2007).

Univariate analysis

Graphical display of the survival curves is generally quite useful to obtain an overall comparison of the experiences of groups subjected to different exposures (Fig. 5.6.2). There are two different ways to measure the association between exposure and survival, which correspond to horizontal (i.e. relative time) and vertical comparisons (i.e. relative hazard) of survival curves. The first one is the relative times defined as $t_i(p)/t_0(p)$, where $t_i(p)$ corresponds to the time taken by p per cent of group i (for $i = 0, 1$) to develop the event. The second one is the relative hazard, defined as $h_i(t)/h_0(t)$, where $h_i(t)$ is the hazard for the i th group (for $i = 0, 1$) at time t . If exposure shortens survival, the relative time will be less than one and the relative hazard will be greater than one. If the relative times are independent of p and/or the relative hazards are independent of t , the times and/or the hazards are said to be proportional. In such cases, the relative times and/or hazards will be constant across all values of p and/or t , respectively. Since the percentiles are relative to the whole cohort but the hazard function is conditional on survivors, proportionality in one does not imply proportionality in the other. Methods based on parametric

models (e.g. lognormal regression) are more amenable to estimation and testing of relative times (e.g. to compare, for instance, the median survival time in exposed and unexposed) and they can also provide measures of relative hazards. Semi-parametric methods based on the proportionality of hazards focused attention to estimation and testing of relative hazards but caution must be exercised because proportionality of hazards is seldom attained.

There are hypothesis-testing procedures to assess whether the differences between two or more survival curves are statistically significant. The most commonly used is the logrank test (Peto et al. 1977), which assumes that the hazards are proportional and tests whether the relative hazard is equal to one. It is equivalent to the Mantel–Haenszel (Mantel and Haenszel, 1959) statistic for the combination of tables constructed at each time an event occurs whereby the table describes how many individuals were at risk at that time and how many of them developed the event from each group being compared.

Multivariable analysis

In the context of survival analysis, the most used method of multivariate analysis is the proportional hazards regression (Cox 1972). The semiparametric proportional hazards regression model corresponds to the hazard of the group with covariates representing exposures and confounders $x_1 = x_2 = \dots = x_K = 0$ (i.e. the reference group) being completely arbitrary, and the hazard of the group characterized by any other values of x_1 to x_K being a fixed multiple of the hazard of the reference group according to a linear combination of the covariates. Specifically, the hazard of the group with covariates x_1, x_2, \dots, x_K denoted by $h_x(t)$ is $h_0(t) \exp(\beta_1 x_1 + \beta_2 x_2 + \dots + \beta_K x_K)$. The interpretation of the parameters is directly linked to relative hazards. In particular, if we have two groups of individuals described by the constellation of covariates taking values x for one group and x^* for the other, the hazard at time t of the group described by x^* relative to the hazard at the same time of the group defined by x (i.e. the relative hazards) is given by $RH(t) \equiv \exp\left[\sum_{k=1}^K \beta_k (x_k^* - x_k)\right]$. Because such an expression does not depend on t , the relative hazard is constant (i.e. the hazards are proportional). In particular, if x and x^* only differ in one unit in the k th covariate

Fig. 5.6.2 Proportion AIDS-free by plasma HIV-RNA (copies/mL).

Source: data from Mellors JW et al., Prognostic Value of HIV-1 RNA, CD4 Cell Count, and CD4 Cell Count Slope for Progression to AIDS and Death in Untreated HIV-1 Infection, *Journal of the American Medical Association*, Volume 297, No. 21, pp. 2349–50, Copyright © 2007 American Medical Association. All Rights Reserved.

(i.e. $x^* = x_1, x_2, \dots, x_k + 1, \dots, x_k$), then the relative hazard of the x^* group to the x group is simply $RH(t) \equiv \exp(\beta_k)$.

When investigators from a cohort study are not only interested in relative hazards but also in describing the underlying hazard with the aim of characterizing mechanisms and the desire to quantify how exposures modify the magnitude of event-free times, parametric models are a more attractive option (Cox et al. 2007). To carry out parametric analyses of time-to-event data, the generalized gamma distribution offers a succinct yet flexible family of distributions. The generalized gamma distribution $GG(\beta, \sigma, \kappa)$ has three parameters whereby the location parameter β governs the value of the median for fixed values of σ and κ ; the scale parameter σ determines the value of the interquartile ratio (i.e. $IQR = 3rd \text{ quartile}/1st \text{ quartile}$) for a fixed value of κ and independently of β ; and the parameter κ determines the percentiles of the standard $\beta = 0, \sigma = 1$ generalized gamma. The generalized gamma contains commonly used parametric models in that the particular cases when κ is zero and one correspond to the log-normal and Weibull models, respectively. More importantly, the parameters κ and σ together determine the *type* of hazard function and yield a graphical taxonomy of the rich variety of hazards covered by the generalized gamma (Cox et al. 2007). Specifically, the taxonomy shows that the generalized gamma family includes all four of the common types of hazard functions: increasing, decreasing, U or bathtub shape, and inverted U or arch shape. More importantly, the p th percentile of the generalized gamma $t(p; \beta, \sigma, \kappa)$ can be expressed in terms of the three parameters by the simple equation $t(p; \beta, \sigma, \kappa) = e^{\beta} [t(p; 0, 1, \kappa)]^{\sigma}$ which dissects the role of each of the three parameters in determining the percentiles of the distribution (i.e. the p th percentile of the standard ($\beta = 0$ and $\sigma = 1$) generalized gamma with shape κ elevated to the power σ and multiplied by the antilog of β yields the p th percentile of $GG(\beta, \sigma, \kappa)$).

The conventional generalized gamma regression model corresponds to $GG(\beta'x, \sigma, \kappa)$, whereby the distribution of the times for the group of individuals with covariate vector x have different location parameters but same scale and shape. In this case, the relative times of the group with covariates x^* to the group with covariates x are constant (i.e. proportional times) and are equal

to $\exp[\beta'(x^* - x)]$. Lack of proportionality of times can be easily incorporated by allowing σ to depend on covariates and full generalization of the model can be accomplished by further allowing κ to depend on covariates. Software is commonly available to implement generalized gamma regression in its full general form (e.g. `streg` command in STATA).

An example of the richness of parametric regression analyses for survival data is illustrated by Schneider et al. (2005), who used data from the MACS cohort of homosexual men and the WIHS cohort of women to characterize the changing pattern of survival after development of clinical AIDS from 1984 to 2004 when different antiretroviral therapies were introduced. Table 5.6.5 presents the relative hazards obtained from a multivariable Cox proportional hazards regression model and the relative times obtained from a multivariable Weibull regression model. Substantial differences in survival were seen between the last two HAART eras (July 1998–June 2001 and July 2001–December 2003) and the no/monotherapy era (prior to 1989); the time from AIDS to death (adjusted by age, sex, type of AIDS diagnosis, and CD4 cell count at diagnosis) expanded by eightfold and 11-fold in the two HAART eras, respectively. This analysis illustrates the role that cohort studies can play in providing measures of the effectiveness of interventions at the population level.

Longitudinal data analysis

The two analytical strategies explained in the preceding subsections (person-time and survival analysis) are the tools regularly utilized for the analysis of the results of a typical epidemiological cohort study when the dependent variable is the occurrence of an event such as disease or death. However, it is often the case that the dependent variable of interest in a cohort study is not the occurrence of an event but the trajectory of a determined biomarker such as blood pressure, weight, leucocyte count, viral load, glomerular filtration rate, pulmonary function, C-reactive protein, or CD4 cell count.

To illustrate the power of longitudinal data in cohort studies collecting data at regularly scheduled visits, we used data collected at semi-annual visits by the Multicenter AIDS Cohort Study from 1984 to 2006. The person-visits of interest were those happening after the first time individuals tested positive for antibodies to HIV and with data on therapy received, CD4 cell count (a marker of immunosuppression), and HIV-RNA (copies of HIV per mL of plasma). The objective was to describe the distribution of HIV-RNA in four categories of CD4 cell count using 200, 350, and 500 cells/mm³ as cut-off values and in four categories of therapy according to whether the participant at a given visit was not on any therapy, was just receiving antiretroviral therapy but not a triple combination, or was receiving triple combination therapy (HAART) and the visit occurred within 3 years or after 3 years from initiation. Two measures of HIV-RNA were used: (1) the median HIV-RNA and (2) the percentage of person-visits in a given category of CD4 cell count and therapy with undetectable HIV-RNA (i.e. <50 copies/mL). Fig. 5.6.3 uses a diamond-shaped equiponderant graphical display of the effects of CD4 cell count and therapy on HIV-RNA whereby the shaded area on each square is proportional to the HIV-RNA (Li et al. 2003). Both panels show the great effectiveness of HAART in suppressing viral replication in all categories of CD4 cell count.

Table 5.6.5 Descriptive statistics, adjusted relative hazards, and relative times for survival after an initial AIDS diagnosis in five calendar periods from July 1984 to December 2003

Variable	Calendar period				
	July 1984–Dec 1989	Jan 1990–Dec 1994	Jan 1995–June 1998	July 1998–June 2001	July 2001–Dec 2003
Therapy era	No/monotherapy	Monotherapy/ combination therapy	HAART introduction	Short-term stable HAART	Moderate-term stable HAART
Number seen	633	660	472	496	464
% women	NA ^a	NA ^a	65%	72%	74%
Incident AIDS	633 (100%)	660 (100%)	472 (100%)	143 (29%)	57 (12%)
Median (IQR) ^b date of AIDS diagnosis	Oct 1987 (April 1986–Dec 1988)	April 1992 (Feb 1991– June 1993)	Jan 1996 (July 1995–Nov 1996)	Nov 1996 (Dec 1995– Sept 1998)	March 1997 (Jan 1996–Oct 1999)
Median (IQR) ^b age at AIDS diagnosis	36.5 (32.1–41.1)	39.7 (35.3–43.9)	39.7 (34.5–44.5)	39.8 (35.1–44.8)	40.1 (35.6–45.2)
Median (IQR) ^b CD4 cell count at AIDS diagnosis	141 (64–273)	90 (35–194)	196 (78–390)	241 (117–439)	268 (130–456)
Number of person-years	685	912	796	1156	992
Deaths number	388	445	109	71	44
% of person-years	57%	49%	14%	6%	4%
Relative hazard ^{c, e} (95% CI)	1	0.65 (0.55, 0.77)	0.21 (0.15, 0.28)	0.08 (0.06, 0.13)	0.06 (0.03, 0.10)
Relative time ^{d, e} (95% CI)	1	1.42 (1.24, 1.62)	3.57 (2.77, 4.61)	7.82 (5.86, 10.45)	10.65 (7.66, 14.80)

^a NA, not applicable since WIHS began in October 1994.

^b IQR, inter-quartile range.

^c Results of Cox proportional hazards regression.

^d Results of Weibull regression under the assumption of proportional survival times.

^e Adjusted by age at AIDS diagnosis, type of AIDS diagnosis, gender, and CD4 within 1 year prior to AIDS diagnosis.

CI, confidence interval; NA, not applicable.

Fig. 5.6.3 Median HIV RNA (copies/mL) and per cent with HIV RNA ≤50 copies/mL in HIV infected individuals according to CD4 cell count and antiretroviral therapy. Multicenter AIDS Cohort Study, 1984–2006.

Methods for the analysis of longitudinal data can be broadly classified in three categories: marginal, conditional, and random effects models. The primary aim of the marginal approach is to combine the multiple cross-sections corresponding to visits so as to provide the most efficient summary of the cross-sectional relationships between exposure and disease. In this approach, the longitudinal component is typically incorporated by including age or time since baseline as a covariate for the regression component of the model. Approaches for the incorporation of the correlation between repeated measurements within individuals include parametric (Jennrich and Schluchter 1986) and non-parametric methods, the latter handling the correlation as a nuisance (Zeger and Liang 1992). The primary aim of conditional models is to regress current outcome on past values of the outcome, and current and previous exposures. Classical Markovian models for binary data were introduced in 1979 (Korn and Whittemore 1979) and applied in 1980 to a study of air pollution and asthma (Whittemore and Korn 1980). Extensions for continuous outcomes were used for the study of the effect of cigarette smoking on respiratory function (Rosner et al. 1985). The primary aim of the random effects models is to allow different individuals to have different intercepts and slopes according to components of variance and to provide direct averages of rates of change across individuals. Fig. 5.6.4 depicts the random effects model whereby the population average line has intercept α and slope β and the line for the i th individual has intercept $\alpha + a_i$ and slope $\beta + b_i$ with the departures being random effects. Methods for random-effects models have been provided for Gaussian outcomes (Laird and Ware 1982), binary outcomes (Kupper and Haseman 1978), and for event-in-person-years outcomes (Breslow 1984).

When data are longitudinal assessments of a biomarker (e.g. pulmonary function, blood pressure, viral load of an infectious agent), linear models for normally distributed biomarkers allowing for both fixed and random effects (i.e. mixed effects) are apt to describe

the probabilistic structure of the data. In the simplest case of two groups (i.e. an exposure taking the value zero or one) with linear trends over time, the fixed effects describe the two average lines for each group. That is, for the unexposed group, the average biomarker trajectory is given by $\beta_0 + \beta_1 t$, and for the exposed group, the average biomarker trajectory is given by $(\beta_0 + \beta_0^*) + (\beta_1 + \beta_1^*)t$. In this case, β_0^* represents the fixed effect of exposure on the levels at baseline and β_1^* represents the fixed effects of exposure on the rates of change of the biomarker over time. The random effects allow individuals in each of the two groups to vary randomly around the average lines of the fixed effects (i.e. each individual has his or her own line that varies randomly from the average line as depicted in Fig. 5.6.4) (Laird and Ware 1982).

Joint analysis of survival and longitudinal data

Since the occurrence of an end point in a cohort study typically marks the end of follow-up in the study, the trajectories of participants who develop end points will typically be shorter than those who remain event-free. When subjects leave the study for reasons related to the effects of exposures and/or the progression of disease, the longitudinal data will be subjected to informative dropout. If the biomarkers of interest have greater changes among those who develop end points, a separate analysis of the longitudinal data may yield biased estimates of the rates of change of the biomarkers as they are unduly weighted towards longer and less changing trajectories. A joint model of the time-to-event data and the longitudinal biomarkers data aims to properly describe the relationships between exposures and the two distinct but related outcome processes. For longitudinal data, a joint model must take into account not only the dependence resulting from repeated measurement of the same outcome, but also the association between the different outcomes, all measured on the same individual. A solution to this problem has been provided by the development of shared-parameter models, in which the necessary

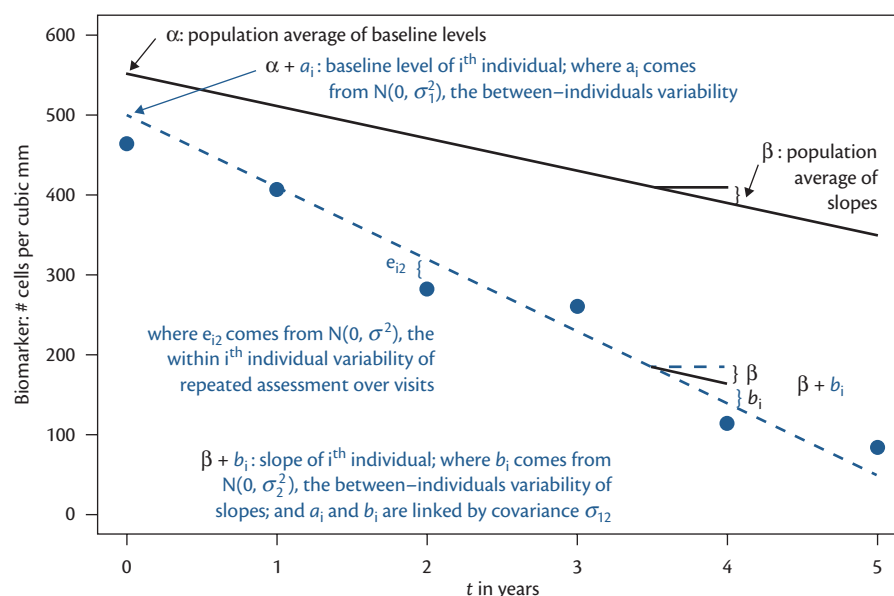

Fig. 5.6.4 Linear model with random intercepts and slopes for the analysis of longitudinal biomarkers data from cohort studies. Population averages in black and random departure of the line of the i th individual in grey.

dependence structure between the two types of data is provided by a vector of shared random effects that links all the measurements on the same individual. Typically the two outcomes (end point and markers) are assumed to be independent given the random effects, which results in a relatively simple factorization of the joint likelihood. Parametric models for the marginal distributions of each outcome, as well as the standard assumption of a multivariate normal distribution for the random effects, provide a complete description of the joint likelihood. Statistical software to fit these models is available in standard statistical software packages such as SAS and STATA.

Validity and biases

External validity

External validity refers to the extent to which the results of a cohort study can be extrapolated or generalized to the reference population. When the cohort is composed of volunteers, representativeness may be limited due to the fact that volunteers tend to be different from the general population.

The representativeness or the lack of representativeness of the cohort in relation to the general population is also determined by the inherent characteristics of the sampling framework. Thus, for instance, even in the case that the members of the Framingham cohort were a representative sample of the population of this small town in New England, it is more than dubious that this population was representative of the general population. A sample from Framingham might be representative of the population of New England, but perhaps not so of the population of the United States. To address this latter issue, the cohorts in studies of cardiovascular epidemiology undertaken in the latest decade in the United States (CARDIA, ARIC, CHS) included participants from several regions of the country, trying to include populations with diverse social and ethnic composition. Even in this case, the representativeness of these cohorts can be questioned if one intends to obtain inferences applicable to the overall population of the continent or the world.

Internal validity

Even when the representativeness of the cohort is dubious, it is possible that the internal comparison between cohort subgroups (e.g. exposed and unexposed) may be valid. In the Precursors Study, for example, it was observed that the standardized mortality ratio was 54 per cent (see Table 5.6.4), which indicates that the mortality in the cohort of the Precursors Study was almost half that of the general US population of the same sex, race, and age. Obviously, this is due to the fact that this cohort is formed by medical students belonging, in general, to higher socioeconomic strata than the average population, which limits the ability to generalize any estimates of the absolute values of incidence or mortality in this cohort. However, it is reasonable to assume that the *relative* comparison of the mortality in smokers and non-smokers in this population (see Table 5.6.3) is valid, or in other words, that the magnitude of the bias that affects the absolute value of mortality given the lack of representativeness of the cohort is proportionally similar in both groups; under these circumstances, even a non-representative cohort in the strict sense of the word, can yield unbiased estimates of the relative risk (or SMR in this case).

In cohort studies, the internal validity is based not only on the comparability of the selection process of exposed and unexposed when the cohort is established, but also on the comparability between the subjects who are lost to follow-up and those who continue under observation in the study. If the participants who are lost to follow-up have a different survival experience compared to those who remain under observation, the overall estimates of survival are biased (i.e. do not accurately represent the survival experience of the population in the original cohort) and special methods are required to avoid the biases due to informative censoring (Robins and Finkelstein 2000; Howe et al. 2011).

Biases

In the evaluation of the possibility of biases due to the losses to follow-up, it is important to consider which types of losses have occurred. The biases due to differential losses to follow-up in a cohort study are conceptually analogous to the *selection biases* that affect case-control or other types of epidemiological studies.

There are other biases than can affect the internal validity of a cohort study. Among the information biases, one type of bias that could affect these types of studies is *surveillance bias*. This bias is present when the persons exposed to a determined risk factor are more carefully monitored or watched over than the persons without that factor. If the disease has a long subclinical phase, this can make the magnitude of the association between that factor and the disease exaggerated. Thus, for example, diabetics are generally subject to periodical check-ups in which blood pressure is taken. Because in the natural history of hypertensive disease there exists a long asymptomatic phase and hypertension is much more likely to be diagnosed in diabetic persons given their periodical clinical assessment, it is possible that part of the strong association that exists between diabetes and hypertension is due in part to a surveillance bias. Even in cohort studies in which information is collected in a systematic form, if the observer knows the history of the participant, he/she can evaluate the presence of the disease in a biased form (*observer bias*). These biases are removed in large part in cohort studies in which a rigorous protocol for collection of information (preferably blinded) and well-trained observers exist.

As in all epidemiological studies, the presence of errors in classification of the participants regarding the presence of the exposure or the occurrence of the disease under study may generate *bias due to misclassification*. When the errors in the determination of disease occurrence are equal in exposed and non-exposed, or when the errors in measurement of the exposure are not differential between diseased and non-diseased, the bias is generally (but not always) conservative; that is, towards the underestimation of the true association (Flegal et al. 1991; Mertens 1993).

Applications and conclusions

Even with the potential limitations regarding internal and external validity discussed in the previous section, the cohort study constitutes the design of reference for all other designs in observational epidemiology. Cohort studies are free from certain types of biases that complicate the interpretation of cross-sectional and case-control studies (Schlesselman 1982), as, for example, recall bias (different recall of the exposure in cases and controls) and cross-sectional bias (when there is a different duration of disease in exposed and unexposed). The cohort design is more powerful

for the establishment of the temporal relationship between cause and effect, one of the classical criteria for causality (Hill 1965).

Another advantage of cohort studies is the possibility of studying the occurrence of several events in addition to that initially planned. Thus, for instance, the Framingham cohort has been the basis for the investigation of several hypotheses in addition to those conceived in the initial aims of the study (Kannel 1990) as, for example, the relationship between several factors and cancer (Kreger et al. 1991), senile dementia (Bachman et al. 1993), cognitive function (Elias et al. 1993; Rhoda et al. 2006), osteoporosis (Hannan et al. 1992), hearing defects (Gates et al. 1990), kidney function (Culleton et al. 1999), pulmonary function (Wilk et al. 2009), healthcare preferences, and others. Furthermore, cohort studies are a platform to expand the initial scientific scope of the studies as new knowledge is acquired and new questions arise. For example, when the MACS was established in 1983, not even the causative infectious agent (HIV) had been identified. It was only in 1985, 2 years into the conduct of the study, that HIV was identified and only then baseline samples kept in a repository were tested to find out who at enrolment was infected with HIV. The whole investigation focused on the infectious aetiology as opposed to other potential causes including an environmental exposure or a nutritional aetiology. Another example is provided by the neurological complications of HIV, as at the beginning, there were no neurological manifestations of HIV but, in the course of the epidemic, cases of dementia were recognized among HIV-infected individuals. Thus, a completely new battery of tests and procedures were implemented in the MACS to respond to the challenge of in whom and when cognitive decline ensued in HIV-infected individuals.

Cohort studies have proven to be extremely valuable in many areas of medical research including cardiovascular disease (Dawber 1980), cancer (Doll and Hill 1952; Doll et al. 2005), and infectious diseases (Samet and Muñoz 1998). Cohort data may also be of great use for the development of public policy, such as treatment guidelines. Follow-up of cohorts before interventions are available provides the most appropriate data for the description of the natural history of disease. Furthermore, if these studies continue to collect data after interventions become available, three uses of these pre-intervention data are apparent: (1) as historical controls for assessing and/or confirming the effectiveness of interventions (Jacobson et al. 2002), (2) as a reference point to establish the effectiveness of interventions at the population level once the interventions have been widely implemented (Detels et al. 1998; Muñoz et al. 2000; Schneider et al. 2005), and (3) as a mechanism to identify the subgroups who should receive treatment once an intervention has been proven efficacious in clinical trials (Phair et al. 2002; Cole et al. 2004; Sterne et al. 2009). From the public health perspective, population effectiveness quantifies the reduction of disease achieved by treating the subset of the population that needs therapies the most. In doing so, cohort studies are at the cornerstone of public health and policy (Szklo and Nieto 2012).

Methodology of intervention trials in individuals

Lawrence M. Friedman and Eleanor B. Schron

Introduction to methodology of intervention trials in individuals

An intervention trial, or a clinical trial, has been defined in various ways and may be of several kinds. The International Conference on Harmonisation (1996) defines a clinical trial as:

[A]ny investigation in human subjects intended to discover or verify the clinical, pharmacological, and/or other pharmacodynamic effects of an investigational product(s), and/or to identify any adverse reactions to an investigational product(s), and/or to study absorption, distribution, metabolism, and excretion of an investigational product(s) with the object of ascertaining its safety and/or efficacy. (p. 3)

This definition has the advantage of applying to all phases of a clinical trial (I–IV), as traditionally defined (Friedman et al. 2010). The International Conference on Harmonisation definition has the disadvantage of not including trials of non-pharmacological or non-device interventions (e.g. surgical procedures, diet, or exercise). To encompass trials of all kinds of interventions, and given that even many trials of drugs, devices, and biologics do not neatly fit into the usual phases, it makes sense to think about early and late phase trials. Early phase trials generally address questions such as proper dose or intervention approach, physiological response, tolerance, and toxicity in small numbers of participants. The participants are often healthy volunteers, but may also be people with disease who have not responded to other treatments. The early phase trials inform the design and conduct of subsequent late phase trials. This chapter will mainly address issues relating to late phase trials that use outcomes of clinical interest and are large enough to influence clinical practice. Such a clinical trial may be defined as ‘a prospective study comparing the effect and value of intervention(s) against a control in human beings’ (Friedman et al. 2010, p. 2).

Clinical trials are needed because only rarely is the precise pattern or outcome of a disease or condition known. It is not yet possible to identify all of the genetic and environmental factors that lead to disease progression, recovery, and relapse. Also rare is the treatment that is so overwhelmingly successful that even with a vague understanding of the course of the disease, it is possible to say, in the absence of a control group, that the treatment is obviously beneficial and has few major adverse effects. More often, the treatment, while useful, is less than perfect. Therefore, in order to determine the true balance of potential benefit and harm from a new treatment or intervention, it is necessary to compare people

who have received the treatment with those who have not. Ideally, this comparison will be made in an unbiased manner so that, at the end, any difference seen between those treated and those not treated is most likely due to the treatment.

It has been said that except for systematic reviews, randomized clinical trials (RCTs) provide the highest level of evidence and an evidence pyramid has been developed (Pandis 2011). While true, it has also been acknowledged that RCTs do not have a monopoly on evidence and have limitations. Therefore, interpretation of clinical trial results must be viewed in the context of other kinds of clinical research.

This chapter can only cover some of the key issues in clinical trials. For more extensive discussions, the reader is referred to any of several textbooks (Pocock 1983; Meinert 1986; Piantadosi 2005; Hulley et al. 2006; Friedman et al. 2010) as well as journals such as *Clinical Trials* and *Statistics in Medicine*. The International Conference on Harmonisation documents (available at the official website: <http://www.ich.org/>) should also be consulted.

Ethical issues in intervention studies

The issue of the ethics of conducting clinical trials has generated considerable discussion and debate. Because interventions may be harmful, as well as helpful, and participants are asked to undergo potential hazards, discomforts, and expenditure of time, the question being addressed in any clinical trial must be important. Knowledge of the answer to the question must be worth these possible harms. This is particularly important since many clinical trials are conducted internationally, often with sites in developing countries. The question being addressed by the trial needs to be important in whatever site it is being performed, with the answer of relevance to that site. In addition, many accept that there must be what has been termed ‘clinical equipoise’ (Freedman 1987). That is, there must be uncertainty as to the usefulness of the intervention among those knowledgeable about the intervention. Individual investigators or doctors may have personal beliefs about the benefits of a new intervention. Those beliefs may prevent those investigators from participating in or entering participants into a clinical trial. The uncertainty in the medical community at large, however, and the importance of the question, are used to justify the conduct of the trial.

Informed consent of all study participants is essential. The nature of informed consent may differ in different countries and cultures, but the concept of individual choice to join or not join

a trial must be universal (Nuremberg Code 1949; The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1979; Council for International Organization of Medical Sciences (CIOMS) 2002; World Medical Association 2013).

In addition to informed consent at the beginning of a trial, it is sometimes necessary either to modify the consent and/or to alert participants already in a trial to important new information. This can happen, for example, when an adverse effect that is important, but not so serious that a trial must be stopped, is noted. The Heart and Estrogen/Progestin Replacement Study (HERS), for example, observed an increase in thromboembolic events among the women taking the hormone therapy. This adverse outcome, which was not clearly stated in the consent form as a known risk, was uncommon, but serious. Rather than stop the trial, the investigators informed the participants of the findings and published the information in a 'Letter to the Editor' (Grady et al. 1997). It may also be necessary to re-inform participants when one clinical trial of a similar nature or question or intervention is reported while another is ongoing (US Department of Health and Human Services 2005).

The issue of conducting research in emergency settings or in other situations where informed consent is either not possible or must be delayed until after the intervention is started is a troublesome one. Such research can be extremely important, yet the imperative to only involve those who have understood the risks and volunteered to be subjects is considered by many to be unbreakable. The US Food and Drug Administration provides an exception from the informed consent requirement in limited settings, provided that certain policies are followed (US Food and Drug Administration 2006), as do other regulatory authorities (Interagency Advisory Panel on Research Ethics 2001; European Medicines Agency 2009).

Selection of the comparison group raises ethical issues. Clinical trials may compare a new or unproven intervention against standard or usual therapy, against no therapy, against a placebo, or in combination with standard therapy against placebo in combination with standard or usual therapy. Whenever the comparison is against no therapy or placebo, the ethics of not treating someone in the best possible way are raised. If indeed there is no good treatment, then it is not a problem. But if a treatment known to be beneficial exists, then a control consisting of no therapy or placebo must be carefully justified. This might be possible if there is no appreciable risk to health or discomfort for the time that effective therapy is withheld (Ellenberg and Temple 2000; Temple and Ellenberg 2000). Often, placebo-controlled trials or trials that have no treatment as the control use both the new intervention and the control (placebo or no treatment) in addition to the best-known treatment or standard care. In such trials, the intent of evaluating the new intervention is not to replace an existing one, but to add to it. The ethics of this situation are similar to those where there is no known effective therapy. A more difficult issue exists when a treatment is commonly used in practice, but it is either of unproven benefit or is not the best-known therapy. This latter situation may occur when practitioners do not accept the evidence for the best therapy or there are practical (including financial) barriers to implementing it (Dawson et al. 2009). Regardless of the reason for unproven or non-optimal treatment, some have advocated using usual therapy as a comparison, arguing that it provides the

best test as to whether the new intervention is superior to what is being done (Eichacker et al. 2002). Investigators must consider the ethical issues of not using the best-known therapy as a control and the potential difficulties in interpretation of the results if the control group consists of a variety of interventions (some of which might be beneficial and others useless or even harmful).

Even when there is no known effective therapy, the ethics of using a placebo, and indeed of randomization, have been questioned (Hellman and Hellman 1991). The strictures of abiding by a study protocol reduce a clinician's freedom to do what he or she thinks is in the best interest of the patient. The interests of the individual study participant cannot be sacrificed for those of society. Conversely, it has been pointed out that a clinician's views as to the best treatment are often misguided, that hunches about treatment are not particularly helpful, and that trials can be designed to take into account participant needs (Passamani 1991).

This last point is crucial. Trial design needs to incorporate the highest ethical standards. Whenever there is a potential conflict between the needs of the participant and those of the study, the interests of the participant must take precedence.

Study question

Primary and secondary questions

The most important factor in selection of the study design, population, and outcome measures is the question that is posed. Each intervention study has a primary question that is specified in advance and is used to determine the sample size. As implied by its name, in the usual two-armed study there is typically just one primary question. It is a question that is important to answer and feasible to address. By feasibility is meant the ability to identify and enrol adequate numbers of participants, to employ the intervention in an effective and presumably safe manner, to ensure that there is adequate adherence to the protocol, and to measure the outcome accurately and completely. In addition to the primary question, there may be a variety of secondary questions. Secondary questions may be less important or less feasible to answer. There may be fewer outcomes or the outcomes may be harder to measure. They may help the investigator to understand the mechanism of action of the intervention by examining biochemical or physiological processes.

Study outcomes (also termed end points or response variables) may be of several sorts. One way of categorizing them is as either discrete or continuous. That is, they may consist of the occurrence of an event, such as a myocardial infarction or survival from cancer, or of a measurement, such as level of blood pressure or number of CD4 lymphocytes. For late phase trials, these outcomes are usually clinically important. That is, they may be fatal or serious non-fatal events, or other clinically meaningful conditions such as alleviation of pain, increased functional status, or change in an important risk factor such as cigarette smoking.

Often, primary outcomes are composites of two or more kinds of events. For example, in studies seeking to reduce the incidence of coronary heart disease (CHD), the outcome might be a combination of death from CHD and non-fatal myocardial infarction. Sometimes, occurrence of coronary revascularization procedures might be included. The reasons for using a composite outcome are that it adds events, and therefore will reduce the required sample size, and that the individual events all represent the same

underlying disease. Interpretation of the results, however, can be challenging, particularly if the outcomes are of different clinical importance. It may be particularly challenging if the outcome perceived to be least important is most common, and dominates the analysis or if the comparisons between groups for the separate components trend in opposite directions (DeMets et al. 2006a).

Regardless of the primary outcome, several features pertain (Friedman et al. 2010). First, it must be specified in advance, written in a protocol. Second, it must be capable of being assessed in the same way in all participants. Third, it must be capable of unbiased assessment. Fourth, it must be assessed in all, or almost all, of the participants. As discussed later in this chapter, significant amounts of missing data can seriously affect the interpretation of the trial.

Biomarkers and surrogate outcomes

Clinical trials can require large numbers of participants, last for years, and be expensive. Trials with a continuous variable as the outcome require fewer participants than do trials with dichotomous outcomes. Also, if the outcome can be assessed before a clinical event has occurred, the study may be shorter in duration. Therefore, there is considerable interest in the use of outcomes that are continuous variables that may not, in of themselves, have clinical relevance, so-called biomarkers or surrogate outcomes. A surrogate outcome is one that substitutes for a clinical outcome; it may not, in itself, be important to the participant. An example is blood pressure. Elevated blood pressure is important primarily because it is a risk factor for stroke and heart disease, not because it is generally symptomatic. It has been shown in numerous clinical trials of both diastolic and isolated systolic hypertension that treatment reduces the occurrence of stroke and heart disease (SHEP Cooperative Research Group 1991; Psaty 1997; Staessen 1997). However, not all methods of reducing blood pressure are without risk or are equally effective in all people. Therefore, trials comparing different antihypertensive agents were conducted (ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group 2002; Wing et al. 2003).

Similarly, we know that ventricular arrhythmias are associated with increased risk of sudden cardiac death (Bigger 1984). Therefore, for years it made sense to treat people with antiarrhythmic agents to reduce the occurrence of sudden death in those with heart disease and ventricular arrhythmias. Yet, when clinical trials of these agents were conducted, the results were sometimes unfavourable (The Cardiac Arrhythmia Suppression Trial (CAST) Investigators 1989; Waldo et al. 1995). Ventricular arrhythmia suppression is not a good surrogate for the clinical outcome of sudden cardiac death. Other examples of inadequate surrogate outcomes have been described (Fleming 1994; Fleming and DeMets 1996). Ideal characteristics of a surrogate outcome have been proposed (Prentice 1989) but these are unlikely to be fulfilled. Therefore, judgement as to the usefulness of a surrogate end point must be exercised. For early phase studies that do not attempt to address clinical questions, surrogate outcomes are entirely appropriate. For late phase trials, the kinds of issues that must be considered are the extent of correlation between the surrogate and the clinical event of interest, the ease or difficulty (and cost) of obtaining reliable surrogate outcome measurements on all of the participants, the feasibility of obtaining enough participants to conduct a clinical outcome study, the harm of a possibly wrong answer, and the

urgency of obtaining an answer. With regard to the possibility of an incorrect answer if a surrogate outcome is used, this may be justified in certain circumstances. For example, if the disease or condition is life-threatening, doctors and patients may require less evidence of clinical benefit and may be less concerned with possible harm from an intervention. The results of a trial with a surrogate outcome may be sufficiently persuasive to allow use of the new intervention. Similarly, in truly life-threatening situations, getting an early answer using a surrogate outcome may outweigh the interest in getting a better, but delayed, answer using a clinical outcome. Early trials in AIDS used surrogate outcomes. At that time, unlike the situation today, no proven treatments were available.

Many advocate the use of surrogate outcomes for rare genetic diseases. It may be important to obtain an answer regarding possible treatment efficacy quickly, given that the life expectancy of people with these conditions can be short. Also, it may be too difficult to find and enrol enough patients with the rare condition for a clinical event to serve as the primary outcome. This position is reasonable, but all (researchers, patients, families, regulatory agencies) should understand the limitations inherent in relying on surrogate outcomes.

Efficacy and effectiveness

Intervention studies are sometimes categorized as efficacy trials and effectiveness trials. An efficacy trial attempts to evaluate whether an intervention works under reasonably optimal circumstances. That is, if the active drug is taken as prescribed by essentially all in the intervention group, and if almost no one in the control group takes the active drug, will the drug alter some clinical outcome? An effectiveness trial allows for non-adherence to the assigned treatment; it resembles what is likely to happen in actual clinical practice. Many effectiveness trials may be termed 'practical', 'pragmatic', or 'practice-based' (Tunis et al. 2003). The intervention is typically one that can be easily administered and the outcome is easily measured. Some trials of this sort may have tens of thousands of participants and have therefore been called 'large, simple'. Because these trials are conducted in many sites, often by investigators with limited research experience, there may be less attention paid to quality control of data. It is assumed that randomization and large numbers will lead to balance and provide an unbiased assessment of the effect of the intervention. Unlike effectiveness trials, most efficacy trials will be relatively short, as longer trials would have trouble maintaining optimal adherence (Friedman et al. 2004). The distinction between efficacy and effectiveness trials may sometimes be unclear as it is a continuum.

Trial designs

Parallel design

In a parallel design study, participants are allocated to intervention or control groups and stay in that group until the end of the study. Although the typical study has two groups, one intervention and one control, many have more. Thus, there may be more than one intervention group and even more than one control group. When there are only two groups, the comparison is straightforward. When there are more than two groups, the comparisons can become complicated. For example, if there are three groups, two interventions and a control, there can be up to three main

comparisons—each intervention against the control and one intervention against the other. This has implications for the overall type I error and therefore for the sample size. Conservatively, one would correct for the number of comparisons, in this case dividing the α level by 3. Instead of requiring a p -value of, for instance, 0.05 for significance, each comparison might require a p -value of 0.0167. To maintain adequate power to achieve this level of significance, the sample size will need to increase considerably. The possibly lower event rates in the two intervention groups (assuming benefit from the interventions) will also lead to the need for a larger sample size. If only the comparisons of the two interventions against the control are of interest, there is less penalty, and the three-arm design may be more efficient than initiating two individual studies, as the same control group can be used. Even here, as will be seen in the section on sample size, the control group may need to be larger than if there is only one intervention group.

Factorial design

If there is an interest in studying more than one intervention at a time, a factorial design study may be more efficient than a parallel design. The simplest factorial design is a two-by-two design. This design will have four groups: treatment A plus treatment B, treatment A plus the control for treatment B, control for treatment A plus treatment B, and control for treatment A plus control for treatment B. The last is the only group that has no exposure to either of the interventions being tested. When this design is analysed, there are two primary analyses: the two groups with treatment A versus the two groups without treatment A and the two groups with treatment B versus the two groups without treatment B. It is unlikely that there will be adequate power to look at a single group against another single group. This would usually only happen if both interventions show differences, and are additive. An example where this happened is the Second International Study of Infarct Survival (ISIS-2 (Second International Study of Infarct Survival) Collaborative Group 1988). Factorial designs need not be just two-by-two. There can be more than two groups for each factor, or even more than two factors. In addition to efficiency, an advantage to the factorial design is that one might derive suggestions of differential effect of treatment in the presence or absence of the other treatment. However, this is also a weakness. If these so-called interactions are present, they may make it difficult to discern an overall effect, particularly if they go in opposite directions (Brittain and Wittes 1989). Examples of successful factorial designs, in addition to the ISIS trials (ISIS-2 (Second International Study of Infarct Survival) Collaborative Group 1988; ISIS-3 (Third International Study of Infarct Survival) Collaborative Group 1992), are the Physicians' Health Study (Hennekens and Buring 1989) and the Women's Health Initiative (The Women's Health Initiative Study Group 1998). Interestingly, for a three-arm parallel design, it is generally thought appropriate to adjust the α level for the number of comparisons. For factorial design, however, the usual practice is not to make such an adjustment.

Cross-over design

In the cross-over design, each participant serves as his or her own control (Friedman et al. 2010). In the simplest case, half of the participants would receive intervention followed by control, and the

other half the reverse. The major advantage of this design is the smaller sample size. Because each participant is on both intervention and control, half the number of participants are needed. The sample may be even smaller, because the variability is less than in the standard parallel design. There are disadvantages, however. The most obvious one is that the outcomes must be reversible. A cross-over design is not possible if the primary outcome is mortality or a clinical event. A second disadvantage is that there is an assumption of no carry-over effect from one period to the next. If the effect of the intervention persists into the period when the control is being administered, then the apparent effect may be less than the real one. Often, to minimize the likelihood of carry-over, a washout period is inserted between the actual cross-over periods. Unfortunately, it is difficult to prove that a carry-over effect is absent and a participant has truly returned to baseline.

Adaptive designs

Adaptive design can mean different things (Friedman et al. 2010). As indicated in the section on randomization procedures, it can refer to modifications in the randomization scheme in order to ensure balance among baseline characteristics or to efforts to maximize the number of participants in the study group that is trending better. Data monitoring can also lead to adaptive designs in the sense that trials may be ended earlier than scheduled because of greater than expected effects. A third use of the term refers to adjustment of sample size or study duration depending upon the overall event rate (study groups combined) or other factors used in the determination of sample size. Sometimes, a trial is designed to continue until a minimum number of outcome events has occurred (again, study groups combined), sometimes termed 'end point-driven' or 'event-driven' design.

Studies of equivalency and non-inferiority

Studies of equivalency address whether the new intervention is similarly beneficial to an agent known to be worthwhile. Studies of non-inferiority look at whether the new intervention is at least as good as the standard therapy. Several factors need to be considered in the design and conduct of these kinds of trials. First, it is sometimes difficult to know that a comparison agent is worthwhile. Not all agents proven to be beneficial at some previous time will be so in all circumstances or to the same degree. Thus, what has been termed the 'constancy assumption' may not hold. This is the case with drugs such as antidepressants (Ellenberg and Temple 2000; Temple and Ellenberg 2000). Therefore, simply showing that a new intervention is no worse than the standard one may not truly prove that the new one is better than placebo. Second, 'equivalency' or 'non-inferiority' must be defined. It is not the same as failing to show a significant difference between the two agents. That could happen simply because the study has an insufficient number of participants, or because participants failed to adhere adequately to the treatments. Because the two agents cannot be shown to be identical (an infinite sample size would be needed), the new intervention must be shown to fall within some predefined boundary that is sufficiently close to the standard therapy. Many agents have been declared beneficial when they are shown superior to control by 20 or 25 per cent. Yet investigators often design non-inferiority trials with margins as large as 50 per cent. Defining how narrow the margin of non-inferiority should be will depend on the risks of inappropriately declaring the new

agent to be as effective as the comparator and the feasibility of conducting a trial with a large enough sample size.

Analysis and interpretation of equivalency and non-inferiority trials is somewhat different from interpretation in superiority trials. Failing to show a difference in a superiority trial does not necessarily entitle one to claim non-inferiority to the control or superiority to no treatment. The breadth of the confidence intervals, and the pre-specified hypothesis must be considered. When conducting a non-inferiority trial, therefore, investigators must consider several factors (Friedman et al. 2010; DeMets and Friedman 2012; Piaggio et al. 2012). First, they should use the best available comparator. Using a control that might be less effective than another one, even if that one has been shown to be non-inferior to the best one, can yield misleading results. Second, investigators should select a margin of inferiority that is based on the best estimate of the effect of the comparator. Because the comparator may have been shown beneficial in trials conducted years before in somewhat different populations, conservative estimates are advised. It is essential to take into account what kind of difference between the comparator and the new agent is clinically important to exclude and how big a trial is practical. Third, one must conduct the best possible trial with high adherence and data completeness.

Interventions versus intervention strategies

Not all interventions need to consist of single treatments. Sometimes, intervention strategies may be tested. In some trials of hypertension treatment, a stepped care approach was used (Hypertension Detection and Follow-up Program Cooperative Group 1979; SHEP Cooperative Research Group 1991). The intent was to see if successful lowering of elevated blood pressure resulted in reduction of stroke or heart disease. If the first antihypertensive agent did not adequately lower the blood pressure, another drug was used or added. At the end of this kind of study, it may not be possible to say that a particular drug is responsible for the observed benefits, but rather a strategy. Sometimes, the strategy may incorporate non-pharmacological as well as pharmacological approaches (e.g. diet as well as drug in order to reduce blood pressure).

In trials that compared coronary artery bypass graft surgery against medical therapy (CASS (Coronary Artery Surgery Study) Principal Investigators and their Associates 1983), the comparison was not really coronary artery bypass graft versus medicine. Because, over the follow-up period, a large proportion of the participants in the medical arm received surgery, it was a strategy of early surgery versus surgery later if needed. Yusuf et al. (1994) reported 5-, 7-, and 10-year results from an overview of seven trials of coronary artery bypass graft surgery. At 5 years, 25 per cent of the participants assigned to the medical arms had received surgery; at 7 years 33 per cent had done so; at 10 years, 41 per cent had undergone surgery.

The Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) compared two strategies in patients with atrial fibrillation (AFFIRM Investigators 2002). One strategy attempted to correct the heart rhythm, using a variety of drugs; the other strategy was designed to control the heart rate. Despite the goal, only 62.6 per cent of the rhythm control group

were actually in normal sinus rhythm at the end of 5 years, while 34.6 per cent of the rate control group were in sinus rhythm at the 5-year point. Nevertheless, the comparison of the two strategies addressed the appropriate and important clinical question of whether trying to convert those with atrial fibrillation to normal sinus rhythm was better than controlling the ventricular heart rate. At the end, the rate control group had mortality that was no worse than the rhythm control group, with fewer adverse effects.

These kinds of studies can be important and valid, but the objectives need to be clearly stated. Otherwise, the study may be criticized for not truly making the intended comparisons.

Quality of life, patient-reported outcomes, and cost-effectiveness

Not all study outcomes need be mortality or major morbidity. Increasingly, clinical trials have evaluated outcomes such as quality of life (QOL) (commonly referred to as health-related quality of life (HRQL), well-being, or patient satisfaction), a related concept called patient-reported outcomes (PROs), or the cost-effectiveness of administering a particular intervention as compared with another, either as primary or secondary outcomes.

There are many definitions of QOL. Essentially, QOL is a multidimensional concept that characterizes an individual's total well-being and includes psychological, social, and physical dimensions (Sartorius 1993). Numerous reliable and valid instruments have been developed for assessing QOL, both for a general population and for specific diseases and conditions (Ferrans and Powers 1985, 1992; Ware and Sherbourne 1992; Ware et al. 1995; McDowell 2006). Conceptual models have been developed that include factors that relate to QOL or HRQL (Wilson and Cleary 1995; Ferrans 1996; Guyatt et al. 2007). The key features may include biological and physiological variables, symptomatology, functional status, social and economic factors, and psychological and spiritual factors. Within each of these broad domains are various individual aspects, the nature of which will depend on the specific condition or disease being studied.

Over the past decade, there has been more attention paid to assessment of PROs. PROs are similar to QOL in that they refer to outcomes that the participant directly reports, without the investigator serving as an intermediary (US Food and Drug Administration 2009). Instruments that assess this seek to determine how the participant feels and what he or she is able to do (Cella et al. 2007; PROMIS® n.d.)

Assessment of QOL and PROs in clinical trials may be particularly valuable in cases when an intervention is not expected to alter survival but may affect a participant's perception of well-being. Cost-effectiveness evaluation may be important when interventions are expensive and where the difference between intervention and control on mortality or major morbidity is small. In a comparison of implantable cardiac defibrillators versus antiarrhythmic drugs, cost-effectiveness was a key secondary outcome. Patients with serious ventricular arrhythmias had a significant reduction in mortality from the defibrillator, but the costs were considerably greater (Larsen et al. 2002). Hlatky et al. (1997) compared quality of life, employment status, and medical care costs during 5 years of follow-up among patients treated with angioplasty or bypass graft surgery. Those in the surgical group had a better quality of

life than those in the angioplasty group. Only in a subset of the participants was the cost lower in the angioplasty group.

There are ongoing improvements in methods of measuring and reporting these outcomes. The current status of HRQL (Guyatt et al. 2007), PROs (PROMIS® n.d.), and cost-effectiveness assessment, however, is sufficiently robust that they can be appropriately used as clinical trial end points.

Adverse effects

As noted at the beginning of this chapter, clinical trials are designed to assess the balance of benefits and harms from a new intervention, as compared with another intervention. Incidence of adverse effects comprises an important part of the harms. In the simplest case, adverse effects are simply the reverse of the hoped-for benefit in the primary outcome. But there are many other possible adverse effects, some of which are expected; others are either unexpected or, although expected, are more serious than anticipated. Assessment of adverse effects is complicated by several factors. First, because many are looked at, it may not be easy to say which ones are truly significantly increased and which ones are due to chance. This is particularly the case with unexpected adverse effects. Although it is reasonable to demand clear statistical significance when deciding that a new intervention is beneficial, investigators will generally be less statistically rigorous when assessing safety of study participants. Second, serious but uncommon adverse effects may not occur often enough, even in large trials, to be properly evaluated. Furthermore, the trial may not last long enough for some kinds of adverse effects to appear. These might only be discovered after a drug has been marketed, when many people have been on it for a long enough time. Sometimes, only when a drug is being evaluated for another indication, requiring a larger sample size and a longer follow-up, will an adverse effect become clear. This occurred when COX-2 inhibitors, originally developed to treat inflammation due to arthritis, were studied for their effects on colon polyps (Bresalier et al. 2005; Solomon et al. 2006).

Often, adverse effects are uncovered not during a clinical trial, or even before approval of an intervention by a regulatory agency, but only after the intervention has been used for some time by many thousands or millions of people. Because of the time and size limitations of clinical trials in assessment of adverse effects, a combination of approaches is needed. In addition to careful monitoring of trials, post-trial follow-up may be important, as are meta-analyses of trial results, use of databases and observational studies, and the burgeoning field of pharmacogenetics.

Study population

A key part of defining the question to be answered is specifying the kinds of people who will be enrolled in the clinical trial. That is done by means of eligibility criteria, of which there are various sorts (Friedman et al. 2010). First, eligible participants must have the potential to benefit from the intervention. That is, they must have the condition that the intervention might affect. Implicit in this is having the degree of severity at a time in the disease process that is modifiable. Also, any change in the condition must be detectable. That is, it cannot be so mild or slowly progressing that to detect a change, the study must be too large or last too long to be feasible. Second, participants cannot have known

contraindications to the intervention. Third, they should not have other conditions which would make it difficult to detect changes in the condition of interest. An obvious example is someone who has both heart disease and cancer. If a 3-year study of an intervention for the heart disease is planned and the expected survival due to the cancer is less than that, it is unlikely that the person will contribute to answering the question about heart disease. Fourth, if the study requires participants to return for follow-up visits in order to assess the outcome, people who are unlikely to be able to do so should not be enrolled.

Fig. 5.7.1 shows how the study participants are derived from the general population. People are excluded at various stages, based on the entry criteria. The final stage indicates that there are identified eligible participants who are not enrolled. This is because participating is strictly voluntary as a result of informed consent. Many people decide that they would prefer not to enrol in the trial.

The issue of who is and who is not enrolled in a trial raises the concepts of validity, generalization, and representativeness (Friedman et al. 2010). A properly designed and analysed trial will yield a valid result. That is, it will be possible to say whether or not the intervention is different from or better than the control, in the setting of the kinds of participants who were enrolled.

Depending upon how narrow or broad the study sample is will determine how much the results can be generalized. If the eligibility criteria are highly selective, then the results might only apply to that sort of participant. If the eligibility criteria are broad, with many identifiable kinds of participants, then the results would be more broadly applicable. The reasons for performing one or the other type of study will depend partly on how much is known about the mechanism of action of the

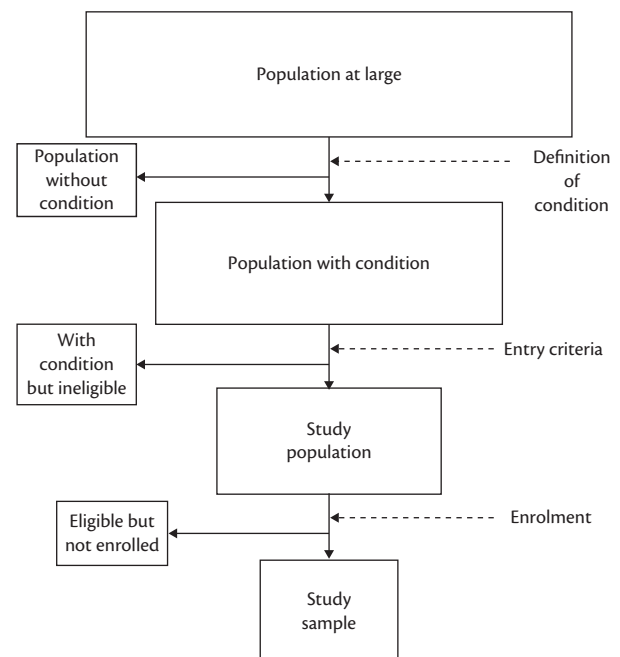

Fig. 5.7.1 Relationship of study sample to study population and population at large (those with and without the condition under study).

Reprinted from Friedman, L.M. et al. (Ed), *Fundamentals of Clinical Trials*, Fourth edition, p. 56, Springer, New York, USA, Copyright © 2010, with kind permission of Springer Science Business Media, <http://www.springer.com/978-1-4419-1585-6>.

intervention. Congestive heart failure may have several aetiologies. If it is known (or surmised) that the intervention only works in heart failure of a non-ischæmic origin, and therefore only such people are enrolled, then the results of the trial would only apply to people with non-ischæmic heart failure. Another reason for a narrowly defined study population might be concern over the risks versus benefits. For example, the first studies of blood pressure reduction were in people with quite elevated pressures (Veterans Administration Cooperative Study Group on Antihypertensive Agents 1967, 1970; Hypertension Detection and Follow-up Program Cooperative Group 1979). Any benefit from treatment would be easier to find because of the greater likelihood of clinical events in this high-risk group. Also, any adverse effects of the intervention would be more likely to be balanced by the benefits. Not until other trials were conducted in people with lower levels of blood pressure was it possible to say with certainty that such people should be treated. The first studies could not be extrapolated to the lower-risk population.

An example of a trial that successfully enrolled a broad population is the Heart Outcomes Prevention Evaluation Study (The Heart Outcomes Prevention Evaluation Study Investigators 2000). In that trial, an angiotensin-converting enzyme inhibitor was evaluated in over 9000 participants with either known vascular disease or diabetes plus a risk factor for cardiovascular disease, but without evidence of heart failure. Regardless of the type of patient, the intervention was found to be highly effective in reducing mortality and morbidity.

No clinical trial is truly representative of the population with the condition being studied. Investigators conduct trials in people to whom they have ready access, rather than a random sample of the population. Eligibility criteria exclude some people for study design reasons and not because it is thought that they would not respond to the intervention in the same way as those enrolled. Additionally, there are always differences between volunteers and non-volunteers. If one is rigid, the results would be applied only to people who are identical in all relevant ways to those in the trial. The key word is 'relevant'. Judgement must be used in deciding to whom the results reasonably apply. Are the characteristics of the patient whom one wishes to treat different in respects likely to alter the effect of the intervention as observed in the trial?

One also needs to ask if the setting or way in which the trial was conducted were so special as to preclude wide generalization of the results. Particularly for trials of surgical procedures or that require other specialized expertise, the trial investigators are likely to be more experienced than the average clinician who will implement the intervention if proven to be beneficial. Therefore, translation of the results of these trials into general practice must be done cautiously, and with due consideration of the skills of the investigators (Flather et al. 2006).

Randomization

The optimal way of allocating intervention or control to clinical trial participants is by means of randomization. Randomization does not guarantee balance in all factors between the groups, but the chances of balance are increased. Unknown as well as known and measured characteristics are likely to be comparable when there is randomization. A properly performed randomization procedure also reduces the opportunity for investigator bias in the

allocation of intervention or control. Finally, randomization guarantees that statistical tests of significance will be valid.

Randomization does not require a one-to-one allocation to intervention or control, only that the allocation be unpredictable. Alternative assignment or assignment based on day of the month (e.g. odd or even) is predictable, and is not equivalent to randomization. Matching on the basis of important characteristics is also not considered randomization. Flipping an unbiased coin to determine whether a participant is assigned to group A or B can be a valid way of randomizing. In practice, however, tables of random numbers or computer-produced random numbers are more often used.

Randomized studies can, by definition, only have a concurrent control group. That is, a historical control study cannot have randomized allocation. This yields another advantage of randomization, namely that the participants are enrolled in the same time period in both the intervention and control groups. Therefore, temporal trends in care or in the nature of the condition being studied are equal in the two groups.

Randomization procedures

Several procedures for randomly assigning treatments to participants have been developed. The simplest are the fixed allocation procedures. If, for example, 20 participants are needed for a study, a coin may be tossed when each participant is entered. However, the likelihood that the number of participants in the two groups will be different (for instance, 12 to 8 or even more extreme) is about 50 per cent. As the sample size increases, the likelihood of such a large uneven split is reduced. If 100 participants are enrolled, the chance of a 60 to 40 split is only about 5 per cent (Friedman et al. 2010).

Blocked randomization is commonly used because of this problem. In blocked randomization, equal numbers of participants in the groups are guaranteed after every several are enrolled. For example, if the block size is 4, and the sample size is 12, then after 4, 8, and 12 participants are enrolled, there would be equal numbers in treatments A and B. This would be accomplished by specifying that each block of four would have two participants assigned to A and two to B. The order within the block of four would be randomized. Thus, it could be ABAB, AABB, ABBA, BABA, and so on. The hazard with this approach is that if the block size is known to the investigator and the treatments are not completely blinded, the last one of the block (and sometimes the last two) can be predicted. Therefore, often, the block size, as well as the order within the block, is random, and the investigator entering the participants is kept ignorant of the block size.

Another advantage of blocked randomization would be if participant entry criteria are modified partway through a trial. In the absence of blocking, even if at the end of entering all participants there are more or less equal numbers in the groups, there may be imbalance in numbers when only some of the participants have been entered. If, because of lagging participant entry, the eligibility criteria are loosened, different sorts of participants may enrol later during recruitment than enrolled earlier. As a result, the characteristics of the participants in group A may differ from those in group B. With blocked randomization, equal numbers are ensured throughout the enrolment period, and changes in entry criteria would not lead to imbalances between the groups in type of participant.

Stratified randomization is a special kind of blocked randomization. Here, the investigator wishes to ensure that there is balance between group A and B, not only in numbers of participants, but in kind of participant. If, despite the randomization process, there is concern that there will be imbalance between groups for one or two key highly prognostic variables, randomization can be stratified on those variables. Thus, within decades of age, for example, blocked randomization would occur. If sex is also a key variable, there would be blocked randomization within each age–sex category. The problem is that even with only two or three characteristics, each one having two or more factors, the number of strata can rapidly increase (Friedman et al. 2010). This can lead to unfilled cells unless many participants are being enrolled. If the sample size is large, randomization will generally lead to good balance, making stratification unnecessary. Therefore, stratified randomization should be done judiciously. If, after the trial is over, it is found that there is a major imbalance in a key factor, an adjusted analysis can be performed. In multicentre trials, randomization is usually done by centre, making the centre one of the important strata. This minimizes the chance that different sorts of participants or different medical practices among centres will confound the results.

In addition to the above fixed randomization procedures, there are various adaptive randomization procedures. In baseline adaptive procedures (also termed adaptive stratification or covariate adaptive randomization), the likelihood of randomization to A or B changes in order to reduce imbalances in selected characteristics. In response adaptive procedures, the likelihood of randomization to one or another group, changes based on the occurrence of study outcomes. Adaptive randomization procedures have not been used as frequently as fixed randomization. For more details of these procedures, see Friedman et al. (2010) and Rosenberger and Lachin (2002).

Blinding

Blinding, sometimes termed masking, is commonly used in clinical trials. In double-blind studies, neither the investigator nor the participant is aware of the intervention assignment. In single-blind trials, only the participant is not informed of the assignment. In unblinded, or open trials, all are aware of the assignment. Ideally, trials should be double-blind. This reduces the opportunity for bias in study management and outcome assessment. For most trials of procedures or lifestyle change, it is not feasible to have anything other than an unblinded design. Here, special efforts to ensure unbiased outcome assessment should be employed.

Sample size

Clinical trials should be designed with adequate power to answer the question being posed. That is, by the end of the trial, there should be enough events or, in the case of a continuous response variable, sufficient precision of the estimate to say with reasonable assurance that the intervention does or does not have the postulated effect. Several factors are considered in the calculation of sample size. For dichotomous outcome studies, these factors are event rate in the control group, expected benefit from the intervention, level of adherence to the intervention, level of adherence to the control regimen, α level, and power. For continuous outcome

studies, the mean and variance of the control and intervention groups, plus the level of adherence, α level, and power, would be the relevant variables.

Various references provide formulas for calculating sample size (Lachin 1981; Lakatos 1986; Wu 1988), as does Chapter 8 in Friedman et al. (2010). In essence, the factors that lead to the need for larger sample sizes in the dichotomous outcome situation are lower control group event rate, smaller benefit from the intervention (or lesser difference that one wants to detect), smaller α , greater power to detect a real difference (smaller β), and poorer adherence (or greater cross-over). Alpha is commonly selected to be 0.05 (two-sided); power is typically 0.8–0.9.

As discussed later, the preferred method of analysis is by ‘intention to treat’. This means that, in general, participants remain in the randomization group to which they have been assigned, regardless of their future actions or the degree to which they adhere to the assigned regimen. To the extent that those assigned to the intervention group fail to comply with the intervention, for example by not taking their medication (often called ‘drop-out’), the expected benefit from the intervention is reduced. Similarly, to the extent that those assigned to the control group begin taking the intervention (often called ‘drop-in’), the control group event rate is altered. The net effect of this non-adherence is a narrowing of the difference between the groups. This, in turn, leads to a larger sample size in order to maintain the same power to detect a real difference. Non-adherence can have an appreciable effect on sample size. A correction factor proposed by Lachin multiplies the needed sample size by $1/(1 - R_0 - R_1)^2$, where R_0 is the drop-out rate and R_1 is the drop-in rate. Because the factor is squared, the sample size increases rapidly as soon as the combined non-adherence rate goes over 20 per cent. Even a combined non-adherence rate of only 10 per cent means a sample size increase of almost a quarter. More complicated sample size formulas take into account the fact that most non-adherence is not linear, but is often greater earlier in a trial than later (Lakatos 1986; Wu 1988). Another factor sometimes considered in sample size calculations is the estimated time for an intervention to make the postulated biological changes. For example, if cholesterol-lowering drugs act at least partly by affecting arterial plaque, then the time for that process to occur (so-called lag time) implies a larger sample size (and a longer study).

As noted in the earlier section on study question, studies of equivalency and non-inferiority may require large sample sizes, depending on what is meant by ‘equivalence’. Because the sample size formula contains the difference to be detected in the denominator, if zero difference is planned, the sample size would be infinite. Therefore, one typically specifies a difference δ . If the two treatments show differences less than this, they are considered equal, or at least they have differences that are unimportant. Sample size formulas for such studies are available (Blackwelder and Chang 1984). It should be emphasized that, unlike studies where a difference is being sought, an underpowered study of equivalency or non-inferiority will lead to the ‘desired’ outcome. That is, it will confirm the null hypothesis of no difference. Even more, poor adherence will enhance the likelihood of seeing no difference for either the primary outcome or for adverse effects.

The needed sample size is an estimate because factors such as event rate and adherence are rarely known for certain. It may be prudent, therefore, to be conservative in the assumptions that

enter into calculating sample size. The disadvantage of being conservative is that increased size or duration leads to increased cost. Also, entering more people into a trial than is necessary to answer the question may put more people at risk than is appropriate. Just as randomization can be adjusted, based on observed outcomes, so can sample size. This chapter is not the place to discuss adaptive sample size methods in detail. Those interested should see Proschan et al. (2006).

Recruitment of participants

A rule of thumb for all late phase clinical trials is that participant recruitment is always more difficult than expected. With medical records and other ways of identifying study participants now being increasingly available electronically, screening can be conducted more efficiently than in the past. At the same time, however, there is increased attention in many countries to privacy concerns (National Institutes of Health 2003a; Peto et al. 2004; Trevena et al. 2006). Therefore, screening and contact of potential study participants must be conducted with proper consideration of privacy rights. This is particularly important in the age of social media. Investigators are beginning to use social media (e.g. Facebook, Twitter) in research to advertise studies, recruit and maintain contact with study participants, and disseminate findings but care must be taken to protect rights.

It is the uncommon clinical trial that finishes enrolment on schedule and the even rarer one that can do so without major recruitment strategy changes. Because recruitment is difficult, it is best to employ multiple strategies and to plan for back-up strategies in advance and to monitor progress closely throughout the enrolment period. Depending on the nature of the study population, back-up strategies would include adding sources of participants (e.g. clinics, hospital units) or disseminating information about the trial more widely, to both medical personnel and potential participants. If sufficient resources are available, the strategies might include adding staff whose primary responsibilities involve enhancing enrolment or increasing incentives. The latter raises ethical questions if the incentives are inappropriate in amount or kind. Paying so-called finder's fees, for example, would not be acceptable.

If participant enrolment remains slow, several options are available. One approach is to extend the time of enrolment. This has the advantage of not changing other study design factors, but the disadvantages of additional cost and delay in answering the question. A second approach is to accept the smaller sample size. Depending upon how large the shortfall is, the reduced power may not be too great. If the power goes from 90 to 85 per cent or even 80 per cent, that can be acceptable. However, if it falls much below 80 per cent, the study is likely to be underpowered. Some have argued that conducting even underpowered trials is useful, as cumulative meta-analyses of similar trials will yield the answers (Antman et al. 1992), but that approach is not recommended here. A third option is to change the entry criteria, so that more people are eligible. Depending on the original criteria, this might be feasible. However, care needs to be taken to make sure that other design assumptions, such as the expected effect of the intervention and the event rate, are not materially changed. In addition, as noted earlier, a blocked randomization scheme needs to be used to ensure that there is no gross imbalance between groups in participants enrolled before and after the criteria change.

A fourth option is to change the study outcome, so that fewer participants are needed to obtain the same number of events. A study may be originally designed with the outcome of death due to heart disease or non-fatal myocardial infarction. Because of limited resources, other remedies for slow participant accrual may not be feasible. It may be decided that the intervention is as likely to affect other important outcomes, such as need for coronary revascularization, as it is to affect myocardial infarction. Adding that event to the primary outcome would increase the event rate considerably, and allow for an answer with fewer participants. In another example, incidence of hypertension may be the outcome in a study looking at prevention of hypertension with weight loss. Instead of using incidence of hypertension as the primary event, mean blood pressure might be used. Going from a dichotomous outcome study to a study using a continuous variable as the outcome will reduce the needed sample size. These sorts of design changes should not be made lightly. They require considerable thought and review. A change in primary outcome should have no input from anyone or any group that is aware of the interim data by treatment assignment. If, because of these changes, the results are not persuasive to the outside community of practising clinicians, there is little point in undertaking them.

Adherence

As discussed in the earlier section on sample size, adherence (or compliance) on the part of participants is a key factor in clinical trials. It can reduce the power of a trial, and, if truly bad, can make the study results uninterpretable. Therefore, most investigators take steps when planning a study to minimize poor participant adherence. One is to design the study so that the regimen is as simple as possible. For medications, once-daily dosing is preferable to more frequent doses. For lifestyle interventions such as diet or exercise, simpler, more easily remembered programmes are better. Shorter trials have better chances of maintaining good adherence than longer ones. A second method is to select participants who are more likely to adhere. One way is by means of a run-in phase prior to randomization. Unless study participants must be enrolled immediately, for example, at the time of an acute event, a run-in period can be used to determine who adheres to the regimen. Potential participants might be given the active medication for several weeks. At the end of that time, only those who took at least 80 per cent (or some other reasonable amount) of the drug would be enrolled. The participants who could not adhere, even over the short term, would not be randomized. This approach has been successfully used in the Physicians' Health Study (Steering Committee of the Physicians' Health Study Research Group 1989; Glynn et al. 1994) and the Women's Health Study (Cook et al. 2005). Angiotensin-converting enzyme inhibitors may cause cough in some people. Therefore, to minimize the drop-out rate after randomization, studies of angiotensin-converting enzyme inhibitors have used a short run-in period to exclude those who might not tolerate the drug (Davis 1998). Excluding potential non-adherers on the basis of other demographic or psychosocial factors has been done, but the evidence that it successfully separates good from poor adherers is unclear (Dunbar-Jacob 1998). Educating potential participants about the trial is not only good practice from an informed consent standpoint, but is likely to lead to the enrolment of participants who are better adherers. Being unduly persuasive in enrolling participants may improve the

recruitment figures, but it can lead to worse adherence statistics. Because the analysis is done on an intention-to-treat basis, the study is more harmed by someone who drops out after enrolment than by someone who does not enrol.

A variety of techniques to maintain good adherence have been tried. Those that appear to be useful are frequent contact and reminders, providing easy transportation and access to attractive facilities, providing continuity of care, providing special medication dispensers, such as calendar packs, and involving family members, particularly when the intervention is lifestyle change (Schron and Czajkowski 2001). Other techniques include attention to aspects of the trial regimen, such as single-dose formulation for medication, intervention schedules made similar to those in clinical practice, and the use of specially trained personnel.

Adherence monitoring has two purposes. One is to be able to advise participants who are not complying with their regimen on how they might improve. The second is to be able to interpret the results of the trial more accurately. The first requires knowledge of individual adherence; the latter only requires knowing how the groups are performing.

Monitoring individual adherence is important, but there is considerable debate about how accurately it can be done, except for interventions that take place entirely in clinics or hospitals (e.g. surgery, vaccine, periodic medication, food feeding studies). Self-reports are simple, but subject to considerable uncertainty. Participants may not remember accurately, and may have a desire to report better adherence than is truly the case. Assessment of activities such as nutritional intake and physical activity are particularly difficult. The use of diaries or other records may help, but still depend on accurate completion by the participant.

For studies involving medication, there are a variety of ways to assess adherence. Pill count is relatively simple, though there are studies that indicate that it over-reports adherence (Rand and Weeks 1998). Participants may forget to return the partially empty containers or may intentionally discard medication that was not taken. Laboratory measures of drug metabolites can be useful, but also may be misleading, as they do not reflect what was ingested long term or show the true pattern of medication usage. Use of special devices that register when a bottle cap is opened has been advocated (Rand and Weeks 1998). Electronic monitoring of this sort can provide a continuous record of dose taking. This probably provides a more accurate measure of adherence, but it is expensive. Even this technique does not prevent a participant from opening the bottle, removing a pill, and then discarding it.

Physiological or biochemical measures that reflect responses to the intervention can be used in some studies. For example, trials of cholesterol-lowering agents which have heart disease as the outcome would periodically measure lipid levels. These are not fool-proof indicators of adherence, as individual responses vary, but they are particularly good at demonstrating that on average, after randomization, the intervention group has a different biochemical profile from the control group. One problem with using these sorts of measures as markers of individual adherence is that they may unmask the group to which a participant has been assigned.

Unless one is willing to go to considerable lengths and spend considerable resources, the simple measures of adherence are probably adequate for most purposes. They will certainly indicate gross problems overall, and allow the investigator to conclude, with reasonable assurance, that the intervention was or was not

administered satisfactorily, and that there is or is not a difference between the groups in intermediate response variables or biomarkers. However, there is no single gold standard for measuring adherence. Furthermore in order to have a valid assessment of adherence, the use of more than one measure is recommended (DiMatteo 2004).

Data and safety monitoring

Data and safety monitoring is an essential part of any clinical trial. If the data become persuasive before the scheduled end of the trial, or if unexpected adverse events occur, the investigator is obligated either to stop the trial or to make necessary design changes. For many trials, the monitoring function is undertaken by a person or group external to the study investigator structure. For masked studies, this helps to keep the investigator blinded. But more importantly, for all trials, an outside group is less likely to have a bias and less likely to want the study to continue inappropriately because of financial or other reasons. The primary function of this group is to maximize participant safety. Secondarily, it helps ensure the integrity of the trial.

In the process of data and safety monitoring, several kinds of recommendations may be made. First, and most common, would be a recommendation to continue the trial without any change. Second would be a recommendation to modify the protocol in some way. Examples might be changing the participant entry criteria, changing the informed consent to take into consideration important new information, changing the frequency of certain tests to better ensure safety, or even dropping from the study certain types of participants for whom it may no longer be appropriate. Third, there might be reason to recommend extending the trial. This could occur if the participant accrual rate is slower than expected or if the overall event rate is much lower than expected. Fourth, there might be a recommendation to stop the trial early.

Data monitoring techniques

Regular data monitoring must be performed for ethical reasons. However, this carries a penalty:

If the null hypothesis, H_0 , of no difference between two groups is, in fact, true, and repeated tests of that hypothesis are made at the same level of significance using accumulating data, the probability that, at some time, the test will be called significant by chance alone will be larger than the significance level selected. That is, the rate of incorrectly rejecting the null hypothesis will be larger than what is normally considered to be acceptable. (Friedman et al. 2010, p. 299)

Therefore a variety of stopping boundaries or guidelines has been developed that maintain the overall prespecified α level. Biostatistics references can be consulted for the details of these methods. In essence, the methods fall into three categories: classical sequential, group sequential, and curtailed sampling. In the classical sequential approach (Whitehead 1997), there is no fixed sample size. Participant enrolment and the study end when boundaries for benefit or harm are exceeded. A theoretical advantage of the classical sequential approach is that fewer participants might need to be enrolled than in a fixed sample size design. This design requires study outcomes to occur relatively soon after enrolment, however, so that decisions about enrolment of new participants can be made. As a result, it may have limited usefulness.

The most commonly used monitoring techniques are the group sequential methods. Here, after a group of participants have been enrolled, or after a length of time, the data are examined. In order to conserve the overall α level, the study is not stopped early even if the nominal p -value (e.g. 0.05) is exceeded. More extreme p -values are required for early stopping. An example of such boundaries is that developed by O'Brien and Fleming (1979), which calls for very extreme results early in a study which gradually become less extreme towards the end. If the study goes to the expected end, the significance value is essentially what it would be without any interim monitoring. An approach proposed by Haybittle (1971) and Peto et al. (1976) uses a constant extreme value throughout the trial, with the usual p -value for significance at the end. Both of these techniques allow the final significance value to be what would be used without monitoring because of the low likelihood of stopping early, given the extreme nature of the boundaries. A modification of these techniques uses what is termed an α spending function (Lan and DeMets 1989). This technique allows for more flexible selection of the times when the data will be monitored.

Another modification of the group sequential methods employs asymmetric boundaries. For many trials, even those that are not one-sided tests of the hypothesis, it would be inappropriate to continue a trial until the intervention is proven harmful, using the usual p -value of 0.05. Therefore, instead of having the monitoring boundary for harm symmetric to the one for benefit, a less extreme monitoring boundary can be developed (DeMets and Ware 1982). Thus, if the one for benefit maintains the overall α at 0.05, the one for harm might maintain it at 0.1, or even less extreme. Even with one-sided tests of hypothesis, an advisory boundary for harm can be implemented, as was the case in the Cardiac Arrhythmia Suppression Trial (Pawitan and Hallstrom 1990).

Curtailed sampling addresses the probability of seeing a significant result if the trial were to continue to its end, given the data at the current time (that is, part way through the trial) (Lan and Wittes 1988). For example, if there is a strongly positive trend with three-quarters of the expected data in hand, one can examine the probabilities of having a statistically significant outcome under various assumptions regarding future data. A reasonable assumption might be that the control group event rate will continue, more or less, as it has been and that the null hypothesis is true. If, under those conditions, the outcome is still significant, there might be reason to stop the study. Conversely, if there is little or no benefit (or a trend towards harm) from the intervention, one might look at how large a benefit would be required from now on to see a significant benefit at the end. If there is little likelihood of that happening, the study might be stopped because continuation would be futile.

Descriptions of stopping decisions in clinical trials have been published (DeMets et al. 2006b). These include stopping early for overwhelming benefit, clear harm, or futility, or if evidence emerges that the study question has been answered elsewhere. A decision to stop a trial early is irrevocable; therefore, such a decision must be made carefully. Whenever a recommendation is made to stop a study early, factors other than whether or not the monitoring boundaries are crossed need to be considered (Friedman et al. 2010). Might the results be due to imbalance in baseline characteristics or to bias in ascertainment of the outcome? Might poor adherence or differential use of concomitant

therapy be important? What might be the impact of outcomes other than the primary one on the interpretation of the conclusions? Are there major unexpected adverse effects that need to be considered? How might other ongoing research affect the results? Will the results be persuasive to others? The issues are not just statistical in nature. If they were, there would be little need for a monitoring committee. Instead, an algorithm could be created which would make the decision. But because the decisions depend on a complex interaction of statistics, understanding of the biological mechanism of action of the intervention, knowledge of other research findings, and judgement as to how the results will be received and interpreted, decisions to recommend continuation or stopping are rarely easy and often second-guessed.

Analysis issues

Whom to include

A purpose of assigning intervention or control by means of randomization is to ensure, as far as possible, that there is balance between the groups on both measured and unmeasured factors. Anything that alters that balance, such as removing from analysis some data from some participants, can induce bias. The reason is that it may be difficult to prove that the cause for the exclusion is unrelated to either a key baseline factor or to the intervention or control. Therefore, the general guideline for analysis is called 'intention to treat'. That is, once randomization has taken place, the data from all participants should be included and counted in the group to which they are assigned. This is in contrast to what has been termed 'per-protocol analysis'. Rather than 'per protocol', the phrase 'on treatment analysis' more accurately reflects what is done.

There are several reasons why one would want to withdraw participants or data from the analysis. First, it may be discovered, after enrolment, that a participant is not truly eligible for the trial. Therefore, that person would not contribute meaningfully to answering the question and, in fact, might confuse the issue by providing incorrect information. Also importantly, it might be hazardous for that person to be taking the intervention. Withdrawing such people from the study and the analysis might seem to be straightforward, but often it is not. If the decision that a person is ineligible is made after adverse effects or a clinical event has occurred, it might be viewed as an effort to manipulate the data. Eligibility criteria are commonly subjective and even in blinded trials there may be clues regarding the group to which the participant was assigned. Therefore, if participants are withdrawn from the trial because they are found to be ineligible, it must be done as soon as possible, before any events have occurred or follow-up measurements performed, and without knowledge of the treatment group. If that does not happen, then the best policy is to leave the participant in the study and analyse the data as if he or she is eligible. If it is possibly dangerous for the participant to be on the intervention, that can be discontinued without removing the person from the trial. If the percentage of ineligible people is small, that should not unduly affect the conclusions. If the percentage is large, such that the study integrity might be affected, then there is clearly a larger problem with the conduct of the trial.

A second reason for withdrawal of participants after randomization is poor adherence. As discussed in the sample size section,

incomplete adherence to the protocol is best handled by increasing the number of people in the trial. Sometimes, however, it is decided to remove non-adherent participants from the analysis. The argument for doing this is that if they have not taken the intervention, there is no way that they can provide information as to its usefulness. The counter-argument is that lack of adherence may be a reflection of not being able to tolerate one or another of the treatments. Therefore, withdrawing poor adherers leads to an underestimate of the adverse effects. It also biases the analysis because those removed from one group are likely to be different from those removed from the other group. There have been attempts to adjust for non-adherence, but these approaches are questionable.

The classic example of how withdrawing poor adherers from analysis can lead to strange results is from the Coronary Drug Project, a trial of lipid lowering in heart disease patients. As expected, those assigned to the active medication group who did not take it fared worse than those who did. But those assigned to placebo who did not take the placebo also fared worse than those who did (Coronary Drug Project Research Group 1980). This outcome could not be accounted for by measured differences between the adherers and non-adherers. Therefore, unknown confounding factors must have been present, as the difference is not attributable to an inert substance. It is best to include the data from all participants, regardless of level of adherence, in the analysis. If, despite the best efforts of the investigator, adherence is so poor as to compromise the integrity of the trial, then that itself says something about the usefulness of the intervention.

Poor quality or, in the extreme case, missing data is a third reason for withdrawing participants from analysis. Every effort must be made to minimize these. If participants are lost to follow-up, or do not return for key outcome measurements, the data will be missing. To the extent that this constitutes more than a few per cent of the total data, the study is severely impaired. The reason, again, is that there is no assurance that the missing data are independent of the treatment. If participants do not return to the clinic because one of the treatments makes them feel unwell, the data in that group will only be from those who are healthier or better able to tolerate the treatment.

Various statistical methods have been proposed to take into account missing data, but none is perfect (Espeland et al. 1992; Proschan et al. 2001). In general, they make assumptions or a range of assumptions about the missing data (sensitivity analysis). They may use prior data from the individual or some average from the group to which that individual is assigned to impute the most likely values for the missing data. One assumption might be that all participants missing in one group had the most unfavourable results while all the other groups had the most favourable results, and vice versa. These techniques can be useful, but as with simply censoring missing data, are limited if the missing data are strongly related to treatment and there are large amounts of missing data. One hopes that regardless of the assumptions made, the overall conclusions are unchanged. If the amount of missing data is so great that, under reasonable assumptions, the conclusions vary, the investigator must question the validity of the study.

The same factors apply to poor-quality data or outliers. Ideally all analyses should be performed with and without including the outliers, as there may be important reasons for the apparently strange data that should not be ignored. One practice that is not

encouraged is substituting data such as prior measurements from an individual for data that are thought to be incorrect or outlying.

Adjustment procedures

Despite best efforts, study groups may turn out to have imbalances in important factors at baseline. In such cases, it is tempting to adjust for these imbalances. Unless the imbalance is large and the factor is highly correlated with the outcome, however, adjustment is unlikely to make a major difference. Simply showing that there is a statistically significant difference in a baseline covariate is not sufficient reason to adjust on that factor. Conversely, large and potentially important differences may not be statistically significant because of small numbers. Furthermore, there may be several covariates that are imbalanced in a similar direction. Individually, they may not be important, but in the aggregate, they may lead to enough of an imbalance that adjustment is useful. In summary, adjustment for baseline imbalances is legitimate, and should be explored if there are apparent differences. Mostly, this is unnecessary. Certainly, if adjustment converts a non-significant result to a significant one, it needs to be interpreted cautiously.

Adjustment for post-randomization variables is strongly discouraged. Level of adherence is one example of such a variable. Others might be biomarkers or similar interim measures of the effect of the intervention, as well as concomitant therapy. Because such variables are, or may be, related to the intervention, unlike the baseline factors, adjustment for them can result in misleading interpretations. Response to an intervention can indicate better prognosis, even in the absence of the intervention (Coronary Drug Project Research Group 1980; Anderson et al. 1983). Adjustment on such a variable can make an intervention appear beneficial when it is not.

Subgroup analyses

In every clinical trial it is tempting to look at the effects of the intervention in subgroups of participants. This is particularly the case with trials that show no significant difference overall. Even without overall benefit, there might be some subsets that indeed benefit. The problem is that with enough creativity, one can almost always find a group that benefits (and a group that is harmed) from the intervention. Even in trials that have significant overall differences, there is a desire to find the types of participants who benefit the most.

It is generally the case that qualitative interactions are uncommon (Peto 1995). That is, an intervention is unlikely to be beneficial in one subgroup and harmful in another. Conversely, it is quite plausible that there are differential relative effects. Some kinds of people are indeed likely to be helped more than other kinds of people. The problem is that unless the subgroups of interest are specified in advance, it is likely that most of the observed differences are due to chance. The best way of confirming that subgroup differences are real is to examine an independent dataset, usually from another trial of the same question. Somewhat weaker is using independent data from the same trial. This can be done if, during data monitoring, a possible subgroup difference is identified. The data accrued during the remaining period of the trial on participants who have not yet had the event can be confirmatory. Other approaches, such as looking at trends in subgroups defined by continuous variables, especially where there is biological plausibility, can also be used.

As noted, with enough imagination, apparent subgroup differences can be uncovered. 'Fishing', or 'data-dredging' is a natural activity, as unexpected subgroup findings can be important sources of new information and new hypotheses. As opposed to raising new questions, however, conclusions should almost never be drawn from subgroups that are not prespecified. The examples of differences based on signs of the zodiac (ISIS-2 (Second International Study of Infarct Survival) Collaborative Group 1988) or similar characteristics are cautionary.

Meta-analyses

A separate chapter in this text is devoted to meta-analyses (Chapter 5.15). Therefore, only a brief summary is provided here. Meta-analyses can be important ways of synthesizing data. They enable researchers to incorporate multiple studies of the same question. Because of the added numbers of participants, they provide better estimates of intervention effects in subgroups. They allow one to put together several small studies to see if a larger study should be conducted to address a question more clearly. They do have potential limitations, however. Most important is the effort expended in collecting all of the relevant studies and the judgement that must go into selection of the studies to be combined. Studies that show benefit from an intervention are more likely to be published (Dickersin et al. 1987). Therefore, if meta-analyses are not done carefully with clear criteria, biases can be introduced. Another limitation is that only some outcomes can be used. Typically, mortality or major morbidity is the outcome of interest. When deciding on whether or not an intervention is useful, other outcomes, such as adverse effects and quality of life, may be important, but are rarely incorporated into published meta-analyses. The ability to perform meta-analyses easily may lead to several inadequately powered studies yielding an overall statistically significant *p*-value. Examples of probably misleading conclusions from these meta-analyses have been observed, once the single large trial was conducted (LeLorier et al. 1997). Any discouragement of the conduct of properly sized trials because of meta-analyses is unfortunate.

Reporting and interpretation

Several guidelines to the proper reporting of clinical trial results have been published and the Consolidated Standards of Reporting Trials (CONSORT) Statement should be consulted for updated guidelines (CONSORT Group 2010). In addition, many journals require that the trial be registered in any of a number of formal registries (De Angelis et al. 2004). In essence, the reporting guidelines call for objective recording of all pertinent aspects. It is recognized that space limitations restrict the amount of information that can be included in a publication. The advent of journal websites, however, allows for the dissemination of supplementary material.

Two related reporting issues concern authorship. Both 'guest authorship' (listing as authors those who did not contribute) and 'ghost authorship' (failure to credit those who actually wrote the paper) are unacceptable.

An ongoing issue is the development of open access online journals. This issue includes not just public access to the journal but access to the data. It should be noted that studies funded by the National Institutes of Health require data sharing plans (National Institutes of Health 2003).

Conclusion

It is not easy to conduct well-designed clinical trials, and there are ethical issues that must be considered. Nevertheless, there is no substitute for good clinical trials in providing important information for clinical use and public health about the possible benefits of interventions. As a result of the development of clinical trial technologies over the past several decades, more clinical decisions are evidence based. Improvements in trial design and analysis are continuing and will have further impacts, as will increasing knowledge about genetics, better understanding of disease aetiologies and processes, and pharmacology.

Methodological issues in the design and analysis of community intervention trials

Allan Donner

Introduction to methodological issues in the design and analysis of community intervention trials

The purpose of this chapter is to address methodological issues that arise in community-based intervention trials. Although the word ‘community’ is often now used in the literature to encompass a wide variety of social groupings, including, for example, schools, workplaces, and religious organizations, the focus here will be largely, but not exclusively, on geographical groupings, such as villages, towns, or entire cities. An intrinsic feature of such trials is that both implementation and randomization at the community level is either the most natural choice or a virtual necessity. For example in mass education trials, it is difficult to provide advice concerning lifestyle modification to some people and not others in the same community without risking experimental contamination. Moreover the interventions administered in such trials often have the potential to affect all or most individuals in a community even though they are actually delivered to only a fraction of residents.

This notion has been recognized explicitly by researchers evaluating the effect of vaccines through the concept of ‘herd immunity’, where immunization is expected to reduce the attack rate among all residents of a community, even though only some individuals have been vaccinated. However, it also may be a factor in other community-based trials that rely on a variety of mechanisms governing human interaction to help modify health risk behaviour. For example, cities were the unit of randomization in the Community Intervention Trial for Smoking Cessation (COMMIT Research Group 1995), a randomized, controlled multicentre trial aimed at adult smokers, at least partly because it was expected that heavy smokers would find it easier to stop smoking in an environment where this practice was made less socially acceptable.

Methodological implications of community-based randomization

Trials that randomize communities or, more generally, ‘clusters’ of individuals to different intervention groups are almost

always characterized by positive intraclass correlation, that is, the tendency for responses among individuals in the same cluster to resemble each other more than the responses of individuals in different clusters. This concept can be equivalently viewed as ‘between-cluster variation’, which reflects the natural variation among clusters that exists even in the absence of an intervention effect. That is, the higher the degree of intraclass correlation, the greater the degree of between-cluster variation.

The reasons for between-cluster variation are diverse, usually cannot be disentangled without an extensive quantity of empirical information, and may be induced either externally or internally. As an example of externally induced clustering effects, differences in smoking by-laws across communities may affect the relative success of smoking cessation programmes. As a second example, differences in socioeconomic status may be related to variation in the success of community-based education programmes. However, clustering effects may also be internally induced, as when individuals with respiratory problems migrate to dry climates or elderly individuals migrate to warm climates. Such effects may also arise simply through the interaction of individuals living in close proximity.

Whatever the source of the clustering, it is now well accepted that it must be accounted for at both the design and the analysis stages of the trial. Failure to account for the clustering in the estimation of trial power may lead to an elevated type II error (caused by a lower level of statistical power than planned for), while failure to account for it in the analysis stage may lead to an elevated type I error (higher rate of false significant differences than planned for). Thus there are two potential pitfalls operating on parallel tracks—if an important intervention effect is present, the probability of detecting it is reduced, while if the effect of intervention is non-existent, the probability of falsely detecting it is increased. As Cornfield (1978) stated, ‘Randomization by cluster accompanied by an analysis by individual (without adjustment for clustering) is an exercise in self-deception, however, and should be discouraged’ (p. 101). He might also have added a similar caution concerning the estimation of trial power.

A recent review of design and analysis strategies employed in cluster randomized trials was presented by Varnell et al. (2004),

who surveyed 60 articles published in the *American Journal of Public Health* and *Preventive Medicine* from 1998 to 2002. Their review showed that only 15 per cent of these articles reported evidence of using appropriate methods of sample size estimation, while 54 per cent reported the use of appropriate analytic methods. These discouraging results are also fairly close to those found in a similar review published almost a decade earlier by Simpson et al. (1995).

Impact of the intracluster correlation

The intracluster correlation coefficient ρ may simply be defined as the standard Pearson product-moment correlation between any two observations in the same cluster. In community intervention trials, where negative values of ρ are usually regarded as implausible, ρ may be equivalently defined as the proportion of overall variance in the trial outcome that may be attributed to variation among clusters. More formally, we may define $\rho = \sigma_B^2 / (\sigma_B^2 + \sigma_W^2)$, where σ_B^2 represents the variance component among clusters and σ_W^2 represents the variance component within clusters. Letting $\sigma^2 = \sigma_B^2 + \sigma_W^2$ denote the overall variance of the outcome measure, we may then write $\sigma_W^2 = \sigma^2(1 - \rho)$, showing how the degree of resemblance among responses within a cluster increases with ρ . Equivalently, higher values of ρ lead to increased variation among clusters for a fixed value of σ^2 .

It is also possible to interpret clustering effects in community-based trials in terms of 'effective sample size'. Consider a trial randomizing k communities of size m to each of two intervention groups. If $N = km$ denotes the total number of individuals per group, then the effective sample size per group is given by $N/[1 + (m - 1)\rho]$. Thus when ρ achieves its maximum value of 1.0, the total amount of information available from each cluster is no more than that provided by a single individual, while at $\rho = 0$ each individual in the trial provides an independent piece of information.

The factor $VIF = [1 + (m - 1)\rho]$ is sometimes referred to as the 'variance inflation factor' or 'design effect', since it represents the factor by which the variance of a group mean or proportion must be multiplied to appropriately account for the randomization by cluster. It is thus clear that the impact of clustering in any one trial depends not only on the value of ρ , but also on the size of the randomized clusters. Unfortunately this has sometimes been a source of misunderstanding on the part of investigators who have ignored clustering effects simply because the estimated value of ρ was close to zero. Note, for example, that values of ρ less than 0.01 are not uncommon in cluster randomized trials. If such a trial were to randomize clusters containing 100 subjects each, the variance inflation factor is seen to be almost 2.0, implying that the effective sample size is only half that of an individually randomized trial enrolling the same number of subjects.

The effect on type I error of ignoring the VIF in testing the equality of two means using an unpaired t -test has been quantified by Scariano and Davenport (1987). For example, their results show that at $m = 100$ and $\rho = 0.01$, the true type I error rate at a nominal significance level of 0.05 is given by 0.1658, a more than threefold increase. Moreover the inflation in type I error rate for given values of m and ρ becomes even greater when an analysis of variance F-test is used to compare three or more means.

The actual value of ρ in practice will depend on both the outcome measure of interest as well as the size of the clusters randomized.

Although ρ is almost always small in size and positive, empirical evidence shows that it generally declines with cluster size, although relatively slowly. For example, in primary care settings ρ has been found to vary from about 0.01 to 0.05 (Campbell et al. 2000), while for very large communities values of ρ may be less than 0.001.

Some investigators may be tempted to perform a test of significance that attempts to rule out a positive value of ρ , interpreting a statistically non-significant result as an indication that clustering effects are absent. However this strategy is not only conceptually flawed ('absence of evidence does not imply evidence of absence') but is particularly weak in this context given the low power of such tests for detecting small but influential values of ρ .

A detailed discussion as to how to account for the impact of clustering in performing standard statistical tests is presented in the later section 'Analysis strategies in community-based intervention trials'.

Specifying the unit of inference

The previous discussion assumes that the unit of inference for the trial is at the individual level, while the unit of randomization is at the community (cluster) level. However, the literature shows that even for trials essentially evaluating the same intervention, there is considerable diversity in the choice of randomization unit. For example, West et al. (1991) report on a meta-analysis synthesizing the results of trials in which the allocation units included individuals, households, neighbourhoods, and entire communities. However, in each case the choice of randomization unit has been largely a matter of practicality or convenience—the aim of each of these trials has been to investigate the biological effect of vitamin A on child mortality. Therefore it is necessary in each of these trials to consider the impact of the variance inflation factor in both the design and the analysis.

However in other trials, particularly those developed from a policy perspective, the units of randomization and of inference may be the same. For example, Diwan et al. (1995) evaluated a policy of 'group detailing' on the prescribing of lipid-lowering drugs in a trial randomizing community health centres. A primary end point in this study was the number of appropriately administered prescriptions per month, with the health centre serving as the unit of analysis. Therefore standard methods of sample size and analysis were employed with no need to consider the role of the within-centre clustering effects. As a second example, the hospital-based rate of caesarean section was the primary end point in a trial designed to lower the rate of caesarean section at the hospital level in Latin America (Althabe et al. 2004). In trials such as these, where the observed results on any one subject are not of direct interest, the challenges that arise in design and analysis are essentially the same as those that which arise in individually randomized trials.

Failure of investigators to distinguish the primary unit of inference in the planning stages of a trial may lead to confusion in developing the trial protocol. Possibly related to this confusion is the terminology 'unit of analysis error', which implies that an analysis at the individual level is inevitably invalid when clusters are the unit of randomization. In fact, this is the case only if the clustering effects induced by the randomization are not appropriately accounted for.

The role of randomization

Randomized or non-randomized?

The discussion up to this point has assumed that communities will be assigned at random to different intervention groups. The advantages of randomization for community-based intervention trials are no different from those in any comparative trial, including the assurance that each eligible cluster has an equal chance of being assigned to a given intervention group, thus eliminating the risk of selection bias on the part of either the participants or the investigators. Randomization also tends to create groups that are comparable on factors (either known or unknown) that may influence response. Moreover this protection extends not only to community-level characteristics, such as size and geographic location, but also to individual-level baseline characteristics, such as age and gender, provided the entire community (or a random subset of residents) is randomized. However, the probability of substantive imbalance on such characteristics is higher than in individually randomized trials allocating the same number of subjects. Therefore it is important in any one trial to confirm the effectiveness of the randomization by comparing the distribution of both community-level and individual-level characteristics across groups.

In the absence of randomization it is almost impossible to rule out the possibility of selection bias in the allocation of communities to different intervention groups. As a result, the study findings run the risk of lacking credibility, particularly if they are unexpected. However non-randomized community-based trials are still frequently implemented, usually for a variety of practical or ethical reasons. For example, if an intervention has already been implemented on a major scale, or if resources for implementing a new intervention are only available in certain communities, randomization may not be viewed as feasible. In other cases, it may be perceived that non-randomized designs would be easier to explain to public officials and to gain public acceptance, given the resistance to assignment by chance that some individuals have. This points to the importance of being able to communicate the purposes and advantages of randomization to key stakeholders, and to possibly offer incentives for their participation.

There are also some arguments against randomization that are less cogent. For example it has sometimes been perceived that non-randomized designs may be preferable when the number of communities available for allocation is small. However, as pointed out by Koepsell et al. (1992), the availability of a limited number of clusters is not a strong reason to avoid randomization, since the increased probability of imbalance on important prognostic characteristics can be controlled by using stratification or pair-matching in the design. Moreover, the challenge of achieving balance when only a small number of communities in each group are available remains a problem whether randomization is employed or not.

In some studies, systematic allocation of geographically separated control and experimental communities has been seen as necessary to avoid experimental contamination, that is, the spread of an intervention effect to individuals in the control group or vice versa. However if the eligible communities are fairly large, this concern can be at least partially dealt with by subsampling participants within the centre of a randomized community while keeping track of any changes of residence (e.g. see Hayes 1998). Another

approach sometimes used to deal with this problem is to combine groups of similar clusters into larger randomization units so as to reduce the extent to which individuals in different intervention groups are likely to mingle. For example, Moulton et al. (2001) describe the design of a vaccine trial conducted among American Indian populations in which two to four geopolitical units were combined into larger units 'so as to minimize social interaction between the units'. Thus the aim here was to sacrifice the potential gain in precision obtainable by choosing a smaller randomization unit in favour of reducing the possible bias due to cross-unit social interaction. Other practical methods of minimizing contamination while otherwise retaining strong internal validity in the context of randomization are discussed by Watson et al. (2004).

In spite of the lower quality of evidence usually obtained from non-randomized comparisons, it is clear that at the very least they may generate hypotheses that can be subsequently tested in a more rigorous experimental framework. Moreover in the initial stages of an evaluation there is undoubtedly greater scope for more widespread use of relatively advanced approaches such as time-series experiments (e.g. Biglan et al. 2000) when it is felt to be premature to launch a full-scale randomized trial.

Subsampling and the risk of selection bias

In some trials—for example, those randomizing worksites—all individuals in a cluster can be readily identified in advance and followed up. In this case, randomization by community will assure that both cluster-level and individual-level characteristics will be well-balanced between groups, that is, there will be no risk of selection bias at either of these levels. Such balance will also be preserved provided random subsamples of individuals are selected from communities after their initial randomization. However, for practical reasons or even out of necessity, subject recruitment is often done prospectively after randomization in an opportunistic manner, raising the possibility of intervention-related bias. For example, project staff who are responsible for recruiting participants to receive a new and promising intervention may be more enthusiastic or selective in their efforts than are individuals who are assigned to recruit participants into the control group. Torgerson (2001) has argued that such differential recruiting efforts could result in substantial imbalance between intervention groups with respect to both the number of the subjects recruited and their characteristics. Similar imbalances could result if willingness to participate differed by intervention group. In either case much of the benefit of the original randomization may be lost, since then it is only the community-level characteristics that will not be subject to selection bias. In the context of trials randomizing medical practices, where it is routine to identify eligible patients after their practice has been randomized, this phenomenon may be referred to as 'detect and treat bias'.

If eligible subjects in a community cannot be identified before randomization, it may be possible to reduce this bias by ensuring that subject recruitment is done by an individual, ideally one who is independent of the study, who does not have prior knowledge of the group allocation. However, if it is the investigator who has responsibility for identifying the trial participants, he/she should be blinded to group membership until a potential subject is judged as eligible. Jordhøy et al. (2002) describe how serious problems of selection bias arose in a cluster randomized trial of palliative care that did not involve blinded group allocation.

Pair-matching and stratification

The attraction of pair-matching as a design strategy

In some community-based trials it is desirable from both a methodological and logistical perspective not to impose any restrictions on the randomization scheme, that is, to adopt a 'completely randomized' design. For example, Sommer et al. (1986) investigated the impact of vitamin A supplementation on childhood mortality in a trial randomizing over 200 villages in Indonesia to each of two intervention groups. With these many clusters, unrestricted randomization can be expected to offer reasonable assurance that the intervention and control groups are well balanced with respect to important prognostic characteristics. Furthermore any remaining imbalance in either cluster-level or individual-level characteristics related to outcome can be controlled for in the analysis (see 'Adjusting for covariates' section).

However, in most community-based trials budgetary and other resource-based limitations simply do not allow a large number of communities to be randomized. Moreover, the smaller effective sample size characterizing such trials implies that the probability of imbalance on any one such characteristic will be greater than in an individually randomized trial that recruits the same total of subjects. Thus, pair-matching, although not a common design choice for individually randomized trials, has an obvious attraction. With this strategy, communities are first matched with respect to selected baseline characteristics, such as geographic area and size, which are expected to be related to outcome. One member of a pair is then randomly assigned to the new intervention, with the other member serving as a control, thus providing assurance that the groups compared are similar at the outset with respect to important prognostic characteristics.

An example of a matched-pair design is provided by the COMMIT smoking cessation trial first mentioned in the chapter introduction, in which the intervention program was randomly assigned to one of two cities in each of 11 matched pairs, ten in the United States and one in Canada. Matching was done with respect to several baseline characteristics, including community size, population density, demographic profile, and geographical proximity. It is also interesting to note that COMMIT enrolled more than three times the number of pairs that were recruited in the first generation of community-based trials, and, perhaps not coincidentally, was the first to use formal power considerations at the design stage.

Although the matching factors selected in any given trial will naturally vary according to the selected end points, two factors very frequently selected are community size (e.g. small, medium, large) and geographic area (e.g. urban vs. rural). Matching by size is particularly attractive since this factor may serve as a surrogate for other key prognostic factors that are more difficult to match on, such as socioeconomic status or access to healthcare resources (e.g. Lewsey 2004). For example, in trials conducted in developing countries larger communities may be advantaged with respect to certain outcomes simply because they are located closer to central health facilities than communities that are smaller in size. Matching by size is also an efficiency consideration since it provides assurance that the number of individuals assigned to each intervention group will be approximately the same.

Particularly large gains in efficiency may be achieved when it is possible to match on suitably categorized levels of the baseline version of the primary end point. For example, if this end point is an incidence rate, then the ability to match on the corresponding baseline incidence rate (or failing that, on a corresponding prevalence rate) can lead to considerable gains in precision. An interesting illustration of this effect is given by Todd et al. (2003) in the context of several HIV prevention studies conducted in East Africa.

A baseline survey that captures such information is also useful for other purposes, for example, in checking on some of the design assumptions that were used to estimate trial power, and in providing field experience to those staff who will be responsible for the final data collection. In making the decision as to whether it is worthwhile to conduct such a survey, Duffy et al. (1992) point out that pre-trial data may sometimes be obtained with a relatively minor increase in resources as compared to that required to secure the same amount of statistical power through increasing the study sample size. However, the decision as to how much baseline data should be collected should depend on how stable the outcome rates of interest have been in past years, as well as on the cost and ease of obtaining the required data retrospectively.

The efficiency of a matched-pair design is directly tied to the magnitude of the matching correlation ρ_m , which may be defined as the standard Pearson product-moment correlation coefficient between the members of a matched pair with respect to their observed end points. Since the actual gain in efficiency in reasonably large samples may be quantified by the factor $G=1/(1-\rho_m)$, it is clear that high values of ρ_m may bring large gains in precision. For example, the HIV prevention trial reported by Grosskurth et al. (1995) generated a matching correlation of 0.94 as a consequence of effective pair-matching of communities on prior rate of sexually transmitted disease, location (roadside, lakeshore, or island) and geographic proximity. However, this degree of success in pair-matching is unusual, and indeed in some trials efficiency may even be lost relative to that of a completely randomized design. This is because many community-based trials can afford to randomize only a small number of units per group, in which case the available degrees of freedom associated with the test statistic used to evaluate the effect of intervention plays an influential role. For example, a trial with k matched pairs is typically analysed using a paired t -statistic with $k-1$ degrees of freedom, as compared to the $2(k-1)$ degrees of freedom available for an unmatched analysis. While this difference may not be important if $k > 30$, Martin et al. (1993) have shown that it may have very tangible consequences in terms of power if $k < 10$. In this case they conclude that 'matching should be used only if the investigators are confident that the matching correlation is at least 0.20'.

Thus the question may arise as to the efficiency of performing an unmatched analysis of data arising from a matched-pair design. Diehr et al. (1995) have investigated this question, showing that for $k < 10$, breaking the matching and performing an unmatched analysis may in fact result in an increase in power for testing the effect of intervention. However, an important assumption here is that the decision to break the matches is made at the design stage of the trial. Thus it would be inappropriate to base the decision to break the matches on the basis of the observed matching correlation, as this would lead to an elevated type I error.

Another limitation of the matched-pair design that arises even in the presence of effective matching results from its inability to directly estimate the intracluster correlation coefficient. This limitation arises because estimation of ρ requires, by definition, an estimate of the natural variation in response among clusters that are treated the same. However, it is clear that the effect of an intervention within a matched pair is confounded with such variation. Hence in the presence of a positive intervention effect, the usual estimator of between-cluster variation, and hence of the intracluster correlation coefficient, will be biased upwards.

Although the inability to directly estimate ρ in a matched-pair design does not affect the ability of investigators to perform a test of the intervention effect, which is inevitably based on between-stratum information, the lack of a valid estimator of between-cluster variation may serve as a handicap in appropriately powering future trials randomizing the same or similar units. Moreover, as discussed by Klar and Donner (1997), constraints will be placed on the nature of several secondary analyses that can be performed, including the ability to make inferences concerning individual-level covariates.

Given the analytic complexities associated with the pair-matched design, a preferable option under many circumstances may be the 'stratified design', as discussed in the next section.

The stratified design

Stratified designs can be viewed as a more general form of the matched-pair design that allocates several communities in each stratum to either intervention or control. For example, the Pathways intervention trial for the prevention of obesity in American Indian schoolchildren (Caballero et al. 2003) used this design to allocate 41 schools to either a multicomponent intervention or to a control. The investigators created primary strata based on four distinct field centres in the study catchment area followed by the construction of two secondary strata within these centres based on a school's median body fat percentage. Half the schools within each stratum were then randomized to either the intervention group or the control group, resulting in 41 schools distributed among a total of eight strata. As stated by the authors, the choice of a stratified versus a paired design was made 'under the assumption that stratification would provide adequate control for the difference in percentage body fat'.

Unlike the matched-pair design, the stratified design allows some degree of cluster-level replication in each combination of treatment and stratum. As pointed out by Klar and Donner (1997), this provides greater flexibility in the statistical analysis, since stratum effects may simply be represented by indicator variables in a regression analysis that appropriately adjusts for clustering effects. As discussed in the 'Statistical approaches to estimating trial power' section, such modelling is not possible in a pair-matched design without making special assumptions.

Although in theory the stratified design offers less control over the influence of key baseline characteristics than a pair-matched design that enrolls the same number of clusters, the difficulty in practice of securing adequate pair-matches for all eligible clusters may mitigate this advantage. Moreover, there is reason to believe that 'over-matching' is not uncommon, given that trials enrolling more than 50 matched pairs have been frequently reported in the literature. Since matching can only be effective to the extent that the baseline risk of an event varies across strata, the question may

arise as to whether such a large number of distinct matches can actually be constructed in advance. This suggests, for example, that a stratified design enrolling four communities in each of 26 strata or eight communities in each of 13 strata, may be as efficient as a matched-pair design enrolling two communities in each of 52 strata, while at the same time offering increased flexibility in the analysis and more degrees of freedom for the estimation of error. Although a completely randomized design without any stratification would provide even more degrees of freedom, this may not lead to a gain in power if the strata are wisely chosen.

Other designs

The designs most frequently adopted in community-based research are the completely randomized, matched-pair, and stratified designs. However, increasing attention has been given recently to other designs that randomize communities. The first is the cluster-crossover design in which all participating clusters receive both treatment and control interventions in a sequence determined at random (Parienti and Kuss 2007). The principal advantage of this design is that it eliminates any confounding due to cluster level characteristics. Since each cluster is its own control, it also reduces the total number of clusters that need to be enrolled in the study, although with a considerable increase in study duration. As in standard crossover trials (essentially enrolling clusters of size one), its validity depends on the assumption that carryover effects are absent, that is, that the estimated effects of intervention are independent of the order in which they are assigned. From a practical perspective, it may also be difficult to assure a uniformly timed replacement of one intervention by the other over the course of the study. A review of methods for analysis of cluster-crossover designs is given by Turner et al. (2007).

The second design that is receiving increasing attention is the stepped wedge design which may be considered a variant of the cluster-crossover design (Hussey and Hughes 2007). For this design all clusters eventually cross over (to the alternate intervention), but at different time points. Moreover the clusters cross over in one direction only—typically from control to intervention. Instead what is randomized is the time at which a cluster begins the intervention. A principal advantage of this design is that clusters may be enrolled gradually over time which may be important from a logistical perspective.

The methodological development of both the cluster-crossover and stepped wedge designs is still evolving. For example, numerous approaches to the analysis have been proposed for both designs, with consensus on the optimal approach yet to be reached. We also need much more practical experience with both designs before they can be firmly recommended (Box 5.8.1).

Determining the required size of a trial

Statistical approaches to estimating trial power

The formal assessment of statistical power is now regarded as a fundamental step in the design of any comparative trial and is a staple of discussion in the clinical trial literature. Historically, however, many community-based intervention trials have been designed with little or no consideration of statistical power. This

Box 5.8.1 Common pitfalls in choice of a design

1. Failure to appropriately define the unit of inference.
2. Failure to define inclusion criteria at both the individual and cluster level.
3. Failure to consider matching or stratification, particularly in smaller trials.
4. Failure to appreciate the restrictiveness of a matched pair design on the subsequent statistical analysis.
5. Failure to consider the possibility of selection bias when subjects are recruited after randomization.

may be partly because any trial enrolling hundreds or even thousands of individuals may (erroneously) be perceived as obviously not lacking in power. However, even those investigators who recognized the issue of the smaller 'effective sample size' in cluster randomized trials did not have effective and easily accessible tools for dealing with this problem until the 1980s.

Appropriate sample size formulae are now easily available in both journals (e.g. Kerry and Bland 1998) and in textbooks (Murray 1998, pp. 305–320; Donner and Klar 2000). In their simplest form, they require that standard sample size formulae for comparing means or proportions be multiplied by an estimate of the likely variance inflation factor $VIF = 1 + (m - 1)\rho$. Thus for comparing either two means or two proportions, an investigator may use standard sample size formulas as would be applied in the design of individually randomized trials and multiply the result by an estimate of VIF.

As an example, let $Z_{\alpha/2}$ denote the two-sided critical value of the standard normal distribution corresponding to the desired type I error rate α , and Z_{β} denote the critical value corresponding to desired type II error rate β . Then, assuming the difference in sample means for the experimental and control groups can be regarded as approximately normally distributed, the number of subjects required per intervention group in a completely randomized design is given by

$$n = \frac{(Z_{\alpha/2} + Z_{\beta})^2 (2\sigma^2) [1 + (m - 1)\rho]}{(\mu_1 - \mu_2)^2},$$

where $\mu_1 - \mu_2$ denotes the magnitude of the difference to be detected and m denotes the average cluster size. Equivalently, the number of clusters required per group is given by $k = n/m$. For comparing two proportions P_1 and P_2 , the required sample size may be obtained by replacing σ^2 in the formula by $P_1(1 - P_1) + P_2(1 - P_2)$.

For variable-sized clusters, Manatunga and Hudgens (2001) and Eldridge et al. (2006) have shown that this expression may be replaced by $VIF = 1 + ((cv^2(k - 1)/k + 1)\bar{m} - 1)\rho$, where the coefficient of variation $cv = S_m/\bar{m}$ and S_m is the standard deviation of the cluster sizes. Eldridge et al. (2006) also give some examples of the value of cv for sample sizes typically seen in cluster randomized trials.

In the presence of effective pair-matching or stratification, application of this formula may be expected to be conservative. However, if prior information concerning the matching correlation ρ_m is available, a more precise estimate of the required size

of sample for a matched-pair design may be obtained by multiplying n by $(1 - \rho_m)$. Donner and Klar (2000) provide examples of sample size estimation for each of the completely randomized, matched-pair, and stratified designs.

An alternative approach to estimate trial size is to formulate the problem directly in terms of the coefficient of variation between clusters rather than in terms of the intracluster correlation coefficient. A discussion of this approach is provided by Hayes and Bennett (1999), who also provide a sample size formula for trials in which outcomes are expressed as rates per person-year.

Ensuring the power is adequate

The requirement for an advance estimate of ρ in assessing the proper size of a cluster randomized trial is no different in principle than, for example, the need to have an advance estimate of the standard deviation of the primary outcome variable in an individually randomized trial. However until the 1990s, values of ρ obtained from previous trial data had not been readily available to investigators. Fortunately this problem is now less serious, with many investigators now routinely reporting the estimated value of ρ for a variety of randomization units and outcome variables. Indeed some investigators have now reported such estimates for a range of study results obtained in a particular research area (e.g. Agarwal et al. 2005; Parker et al. 2005; Gulliford et al. 2005).

The review by Gulliford et al. (2005) is particularly notable in that it reveals an approximate linear relationship which holds on the log scale between the prevalence of a trait and the corresponding value of ρ . This suggests that the anticipated prevalence of an outcome variable may be used in some research contexts to make an informed assumption about the magnitude of clustering effects.

It is important to recognize that any particular value of ρ must be interpreted in the context of the trial design and analysis. For example, estimates may be obtained either taking into account the trial stratification factors and/or the individual level covariates adjusted for in the analysis. It is also useful to note that unadjusted values of the intracluster correlation coefficient, which are those most frequently presented, will generally be larger than their adjusted counterparts, implying their future use in sample size estimation will be conservative.

Even with the availability of an appropriate estimate of required trial size, it is useful to conduct a sensitivity analysis exploring the effect on sample size by varying the values of the intracluster correlation, the number of clusters per intervention group, and the cluster (or cluster subsample) size.

The increased attention that has been paid more recently to the formal assessment of the required sample size in the design of community-based intervention trials is particularly welcome given that many of these studies have historically been underpowered and thus found to be inconclusive (e.g. Susser 1995). This is not only because many investigators have not had ready access to the statistical tools needed for this purpose, but also because community-based trials may be particularly susceptible to problems of low power given the nature of the interventions evaluated and the heterogeneity of the populations to which they are administered. For example, many interventions are applied over a wide area on a group basis with relatively little attention given to individual study participants. Thus the risk of both non-compliance and loss to follow-up is exacerbated, particularly since not only

individuals but entire communities are subject to attrition. Moreover many community-based trials are also prevention trials whose aim is to reduce event rates that may already be quite low in a relatively healthy population. The lengthy follow-up time typically required in these trials places a further burden not only on the ability of study participants to show reasonable levels of compliance but also on the efforts of project staff who are administering the intervention over large geographic areas, often with only limited resources at their disposal. Thus it is perhaps not surprising, as stated by Susser (1995, p. 156), that 'generally the size of effects has been meager in relation to the effort expended'.

Some community intervention trials also have to contend with the immigration of new subjects after baseline, further complicating issues of ensuring that study power is adequate (Jooste et al. 1990). Further discussion of this issue in the context of cancer prevention trials is given by Byar (1988).

Since the power available in a given community-based trial is invariably limited by the degree of between-community heterogeneity, one strategy for increasing precision is to establish relatively narrow cluster-level eligibility criteria, for example, by randomizing communities of similar size and socioeconomic status. For example, LaPrelle et al. (1992) enrolled communities in a smoking cessation trial that were known to be similar with respect to racial and educational make-up, while acknowledging the corresponding risk of some loss in generalizability. Similarly, in the HIV intervention trial described in the section 'The attraction of pair-matching as a design strategy', clusters were deliberately selected to be homogeneous for the purpose of increasing statistical power.

For trials such as that described by LaPrelle et al. (1992), where there is some latitude in how the primary outcome variable can be defined, it is useful to recognize that continuous end points (e.g. number of cigarettes smoked per day) generally lead to much more statistical power than their dichotomous counterparts (e.g. quitting smoking or not), although issues of measurement error and ease of interpretability must also be considered here.

As mentioned in the section 'Specifying the unit of inference', some trials are also characterized by a degree of flexibility in the fundamental choice of the unit to be randomized. In this regard, Duan et al. (2000, p. 1470) have remarked that 'it is important to explore new conduits (such as churches) through which community-based interventions can be more effectively delivered to target subpopulations of heightened risk'. This argument recognizes that the choice of randomization unit may directly impact on statistical power through a variety of factors, both tangible and non-tangible.

A common rationale for avoiding individual randomization in the evaluation of a new intervention is to reduce the risk of experimental contamination. However, investigators have also recognized that power losses due to contamination may remain a problem even if intact social groups are randomized, particularly in the case of small adjacent clusters. Aside from its possible role in minimizing contamination, as discussed in the section 'Randomized or non-randomized?', selective subsampling can also be used more directly to increase power. For example, a decision could be made to enrol only neighbourhoods within a larger community that are known to have higher levels of risk factors than the community as a whole. From a statistical perspective, this strategy would be consistent with the well-known effect

on power of increasing the number of clusters in a trial versus increasing the sizes of these clusters. Thus in a trial allocating k clusters of size m to each of two intervention groups, the variance of an estimated event rate \hat{p} is given by $\text{Var}(\hat{p}) = \{P(1 - P)(1 + [m - 1])\}/k$, where P is the value of the true event rate. It is therefore clear that increasing k for a fixed value of m steadily drives the value of this variance to zero, implying that the power of the trial can be increased indefinitely by increasing k . However it is also clear that as m increases for a fixed number of clusters k , $\text{Var}(\hat{p})$ can only be reduced to a limiting threshold value given by $P(1 - P)/k$, thus constraining the maximum power that can be obtained. In fact even when clusters are (hypothetically) infinite in size, the power of a trial may be held below 80 per cent if k is not sufficiently large.

A useful rule of thumb in this regard is that very little increase in power will be obtained for a fixed number of clusters after m exceeds the value $1/\rho$ (Donner and Klar 2004). For example if $\rho = 0.01$, then the increased power obtained by enrolling more than 100 subjects per community will be small. Yet, as alluded to in the chapter introduction, investigators will often have practical reasons for enrolling very large numbers of subjects per community, even if not warranted from a strictly statistical perspective.

Torgerson (2001) and Farrin et al. (2005) have argued that the practice of randomizing intact social groups as a means of minimizing contamination effects may be overused. The argument made by these authors is that the loss of precision associated with cluster randomization often outweighs that which results from the contamination and subsequent dilution of intervention effect that can be expected under individual randomization. However, it must also be recognized that under individual randomization the presence of contamination will serve to bias the estimated intervention effect, a factor which must also be taken into account if the ultimate goal of the investigators is to estimate the magnitude of this effect when the intervention is applied in a non-experimental setting. Other factors to consider here include practical aspects involved in administering the intervention and the importance of reflecting 'real world' conditions while doing so.

If the correlation r between a baseline score and a follow-up score is fairly high, say 0.5 or larger, it would be more efficient to compare net changes in baseline between two intervention groups than it would be to compare the final scores alone. Moreover empirical findings reported by Murray et al. (2000) suggest that the value of ρ estimated from a net change from baseline may be considerably smaller than that corresponding to the final score, adding further to the gain in efficiency. An extension of this strategy would be to take repeated measurements over time in each community. This was done in the REACT trial (Luepker et al. 2000), where the slope of the linear trend over time was defined as the primary end point.

Similar gains in precision may accrue from the incorporation of relevant covariates in the context of regression modelling. The gain in precision obtained by covariate adjustment can be estimated using the correlation coefficient between the outcome variable and the covariate in question. Again denoting this correlation by r , the error variance in a standard model for continuous outcome variables will be reduced by the factor $1 - r^2$, a result also holding approximately for binary outcome variables. (For multiple covariates, r is replaced by the multiple correlation coefficient R .) It is thus seen that substantial gains in efficiency beyond that

formally planned for can be secured if the appropriate covariates can be identified and measured in advance.

Trials allocating only one community to an intervention group and one to a control group are still occasionally reported in the literature. The flaw in these studies is not only one of low power but the questionable validity of the design itself. This is because any effect of intervention is totally confounded with intrinsic differences that are likely to exist between the two communities, even though on face value these communities may appear to be well matched. Thus it is impossible to develop a valid significance test for evaluating the effect of intervention, similar to the difficulty that would be faced in a clinical drug trial randomizing one patient to each of two treatments. Nonetheless this design might be helpful for pilot investigations whose main aim is to examine practical issues such as the acceptability of the intended intervention.

Once the appropriate sample size has been selected using statistical considerations, there remains the practical problem of ensuring that recruitment targets can actually be met. Shadish (2002) points out that this can be a particularly difficult challenge when researchers have had no previous experience with the communities to be enrolled, and cautions in this case that it is particularly important to conduct a pre-study survey that attempts to locate and count potential participants. This advice reflects continuing discussion in the literature that large-scale community-based intervention trials are sometimes launched without performing adequate feasibility studies of the complex intervention components and measurement instruments that tend to characterize these studies. An excellent example of how comprehensive feasibility studies can be used effectively in the planning stages of a large-scale community-based trial is given in a series of articles that describes the pilot phase of the Pathways obesity prevention study (Caballero et al. 2003) (Box 5.8.2).

Analysis strategies in community-based intervention trials

Basic methods of analysis

There are now many statistical procedures with an array of underlying assumptions that can be used to analyse data arising from cluster randomization trials. In this section we provide a limited discussion of some of these procedures. This will be done

separately for completely randomized, matched pair, and stratified designs.

Underlying this discussion are some fundamental principles that apply to most comparative trials. The first of these is that the 'intent-to-treat' approach will be used for the primary analyses, implying that all subjects will be counted in the group to which they have been assigned and that outcome data on all subjects will be included in the analyses. In the context of community-based trials, this implies that once a cluster has been randomized, it must be retained in the allocated intervention group. Thus, the intent-to-treat principle provides a 'real-world' assessment of the effectiveness of an intervention rather than an 'efficacy' assessment reflecting optimal conditions. However, secondary analyses in which certain clusters or cluster members are not counted can be particularly useful for either strengthening the trial conclusions or suggesting that caution be used in their interpretation.

To ensure that the final evaluation of intervention effect is not subject to bias, every effort should be made to obtain outcome data on subjects who, because of refusal or other factors, become characterized as 'dropouts'. Since in spite of an investigator's best efforts outcomes on some subjects will inevitably remain missing, satisfactory methods must be used to handle this problem, as reviewed, for example, by Shadish (2002). These include relatively simple methods of imputation, where a missing data point is replaced by the mean of the remaining observations to more sophisticated methods of multiple imputation (Little and Schenker 1995). A difficulty unique to community randomized trials is that entire clusters may be lost, in which case imputation at the analysis stage is generally not an alternative. Instead every effort must be made in the planning stages of the trial to motivate key decision-makers in each community to undertake all reasonable efforts to prevent a community from suspending their participation in the trial.

In some trials it has been the custom to perform a 'modified intent-to-treat analysis' in which certain subjects are removed on the grounds that treatment-related bias is highly unlikely, while statistical power will be improved. For example, in vaccine trials it is common to remove subjects who fail to receive even a single injection of the vaccine assigned. In this case it is always prudent to perform a secondary analysis that includes all subjects randomized.

The completely randomized and stratified designs

If a completely randomized design is adopted, k clusters (communities) are randomized to each of two groups, usually with a binary or continuous variable chosen as the primary outcome measure. In this case the simplest and perhaps most intuitive approach to the analysis would be to adjust standard procedures such as the chi-square test (for comparing proportions) or the t -test (for comparing means) to account for clustering effects.

We illustrate this approach by considering the comparison of proportions in a completely randomized design. A detailed description of methods for comparing both means and proportions in cluster randomized trials, including examples of all procedures discussed in this section, is given by Donner and Klar (2000, chapters 5–6).

Let m_{ij} denote the size of the j th community assigned to the i th group, $i = 1, 2$; $j = 1, 2, \dots, k$, with $M_i = \sum_{j=1}^k m_{ij}$ denoting the total

Box 5.8.2 Common pitfalls in sample size estimation

1. Over-optimistic expectations regarding the anticipated effect size.
2. Failure to understand the relative roles of number of clusters enrolled versus average cluster size on trial power.
3. Interpreting values of the intraclass correlation (ICC) close to zero as ignorable for the purpose of sample size estimation.
4. Failure to do a sensitivity analysis with respect to the impact of the ICC on study power.
5. Failure to account for possible loss to follow-up and non-compliance at both the individual and cluster level.

number of subjects in group i , and \hat{p}_i denoting the corresponding value of the overall event rate in this group. Then the standard Pearson chi-square statistic with one degree of freedom may

be written as $x_p^2 = \frac{\sum_{i=1}^2 M_i (\hat{p}_i - \hat{p})^2}{\hat{p}(1 - \hat{p})}$. However, application of this

statistic to clustered data is invalid since the assumption of statistical independence required to ensure the validity of this test will be violated. In particular, the effect of applying x_p^2 to data arising from a cluster randomized trial will, in general, lead to an elevated type I error, implying that intervention effects declared as statistically significant may in fact not be significant if correctly evaluated.

Appropriate adjustment of x_p^2 for clustering effects requires an estimate of the underlying intracluster correlation coefficient ρ , which, under the null hypothesis of no intervention effect, may be assumed to be constant across intervention groups. The required estimate may be obtained by pooling the observations in both groups and then applying the 'analysis of variance approach' described by Donner and Klar (1994 and 2000, chapter 6). Let MSC and MSW denote the pooled mean square errors between and within groups, respectively. Then defining $\bar{m}_{Ai} = \sum_{j=1}^{k_i} m_{ij}^2 / M_i$, we obtain:

$$\hat{\rho} = (MSC - MSW) / (MSC + [m_0 - 1]MSW),$$

where:

$$MSC = \sum_{i=1}^2 \sum_{j=1}^{k_i} m_{ij} (\hat{p}_{ij} - \hat{p}_i)^2 / (k - 2)$$

$$MSW = \sum_{i=1}^2 \sum_{j=1}^{k_i} m_{ij} \hat{p}_{ij} (1 - \hat{p}_{ij}) / (M - k)$$

$$\text{and } m_0 = \left[M - \sum_{i=1}^2 \bar{m}_{Ai} \right] / (k - 2).$$

The value of x_p^2 is then adjusted by applying a correction factor which depends on both $\hat{\rho}$ and the values of the m_{ij} . Letting

$C_i = 1 + (\bar{m}_{Ai})\hat{\rho}$, the adjusted chi-square statistic with one degree

of freedom is given by $x_A^2 = \sum_{i=1}^2 \frac{M_i (\hat{p}_i - \hat{p})^2}{C_i \hat{p} (1 - \hat{p})}$.

At $\hat{\rho} = 0$ ($C_1 = C_2 = 1$), it is clear that x_A^2 reduces to x_p^2 , while if all clusters are of the same size m , it reduces to $x_p^2 / [1 + (m - 1)\hat{\rho}]$.

As mentioned in the section 'Impact of the intracluster correlation', values of $\hat{\rho}$ computed as negative are usually truncated at zero, since negative clustering effects tend to be regarded as implausible in cluster randomization trials. It follows in this case that standard methods of statistical analysis may be applied to the trial data.

It is worth noting that the validity of this approach does not require the assumption that the correlation ρ between any two observations in the same cluster is constant (an assumption which in any case would be particularly dubious in the context of trials randomizing entire communities). Rather the only requirement

in this regard is that the average value of ρ is reasonably constant from cluster to cluster.

However, application of the statistic x_A^2 does require that the total number of clusters is sufficiently large to allow ρ to be estimated to a reasonable degree of accuracy. Thus for trials enrolling fewer than ten clusters per group, as is the case in many community-based studies, it may be preferable to restrict analyses to the cluster level, for example, by applying the standard two-sample t -test to comparing the mean event rates in the two groups. Although the required assumptions of normality and homogeneous variance for this procedure are clearly violated, particularly in the presence of variable cluster sizes, there is considerable evidence that the t -test is remarkably robust to such violations (e.g. Donner and Klar 1996).

An alternative is to apply nonparametric procedures such as the Wilcoxon rank sum test or Fisher's two-sample permutation procedure. While the Wilcoxon procedure is computationally simpler, the permutation test uses the actual values of the observed event rates rather than their ranks and therefore tends to be more powerful. Exact statistical inferences for these procedures can be conducted using programs such as Proc-StatXact® (Mehta and Patel 1997). However it is useful to note that both procedures require at least four clusters per group in order to achieve statistical significance at $p < 0.05$, reflecting their relatively weak power.

It is well known that the interpretation of results from any comparative trial is enhanced by their presentation in terms of confidence limits. Following the approach above, an approximate two-sided 95 per cent confidence interval about a difference in proportions may be readily obtained as:

$$(\hat{p}_1 - \hat{p}_2) \pm 1.96 \sqrt{\frac{C_1 P_1 (1 - P_1)}{M_1} + \frac{C_2 P_2 (1 - P_2)}{M_2}}.$$

At $\hat{\rho} = 0$, ($C_1 = C_2 = 1$), this expression reduces to the standard confidence interval about a difference between two proportions. However, the assumption of a common intracluster correlation coefficient, although guaranteed under the null hypothesis of no intervention effect, may not be appropriate for confidence interval construction. In this case separate estimates of ρ may be used in computing the variance inflation factors C_1 and C_2 .

Since the stratified design may be viewed as a replication of the completely randomized design, straightforward extensions of the latter may be used to account for both stratification and clustering effects. For binary outcomes, Donner (1998) and Donner and Klar (2000, chapter 6) have shown how the well-known Mantel-Haenszel test for combining several two-by-two contingency tables may be applied to a stratified cluster randomized design (Mantel and Haenszel 1959). For continuous outcome measures, a weighted t -test procedure may be used, as described by Donner and Klar (2000, chapter 7).

As is the case for the completely randomized design, a stratified permutation test may be applied to this design when the number of clusters is small, as implemented using programs such as Proc-StatXact®. An example is given by Duan et al. (2000), who used this procedure to analyse data obtained from a church-based telephone-counselling trial, where the stratification factors were church characteristics thought to be strong predictors of the primary outcome variable.

In non-randomized community-based trials, the assumption of a common ρ may not be reasonable, although simulation studies

performed by Jung et al. (2001) suggest that moderate differences in the value of ρ from group to group will only slightly disturb the properties of x_A^2 . The ratio estimator approach, frequently used in the field of survey sampling (Rao and Scott 1992), requires no assumptions concerning the intracluster correlation coefficient and therefore may be preferred to x_A^2 in trials that have not employed random allocation. However, a practical disadvantage of this procedure is that it requires many more clusters per group (at least 20) to ensure its validity (Donner et al. 1994).

The matched-pair design

In a matched-pair design the intervention of interest is randomly assigned to one community within a pair (stratum), with the remaining community acting as a control. Since a measure of between-cluster variation is not directly available from the communities within a pair, the test of intervention effect is typically performed using cluster-level procedures such as the paired (one-sample) t -test, in which the error variance is estimated using between-stratum information.

This procedure is natural for testing the effect of intervention on a continuous outcome measure, where it is applied to the differences d_j , $j = 1, 2, \dots, k$, between the two means in the j th stratum, $j = 1, 2, \dots, k$. However it is also frequently used in the case of a binary outcome measure, since, as in the case of the two-sample t -test, research has shown (e.g. Gail et al. 1996) that the paired t -test is very robust to departures from the underlying assumption that the d_j are normally distributed with constant variance.

Let d_j , $j = 1, 2, \dots, k$, denote the difference in means or proportions in the j th stratum, with mean $\bar{d} = \sum_{j=1}^k d_j/k$ and variance $S_d^2 = \sum_{j=1}^k (d_j - \bar{d})^2 / (k-1)$. Then the paired t -statistic is given by $tp = (\bar{d} \sqrt{k}) / S_d$ with $(k-1)$ degrees of freedom.

This procedure was used to test for the effect of intervention in the community-based trial described in the section ‘The attraction of pair-matching as a design strategy’ that was designed to reduce the rate of HIV (Grosskurth et al. 1995). After transforming the observed HIV rates to the logarithmic scale to improve normality, the precision of the analysis was further improved by defining the primary end point as the difference between the baseline rate and the observed 2-year rate.

Some investigators avoid the need to make modelling assumptions in the analysis of data obtained from a matched-pair design by alternatively applying either the Wilcoxon signed rank test or Fisher’s one-sample permutation test. Exact inferences for these procedures may again be obtained using Proc-StatXact®. However both procedures require at least six pairs in order to achieve statistical significance at $p < 0.05$.

Adjusting for covariates

The section ‘Pair-matching and stratification’ discusses how design-based strategies can be used to control for the influence of cluster-level covariates. An alternative is to adjust for both cluster-level and individual-level covariates in the statistical analysis using regression modelling. Although adjustment for aggregated versions of individual-level covariates can be achieved at the design stage (e.g. stratification by percentage of residents with high school education), statistical adjustment at the individual level for that covariate may bring greater efficiency as well as ease of interpretation due to the absence of the well-known

‘ecological fallacy’. Moreover, since the likelihood of chance imbalance on any given covariate in a cluster randomized trial is greater than in an individually randomized trial enrolling the same number of individuals, regression modelling procedures may be essential for avoiding chance confounding. However, this is only possible if those covariates expected to have a strong relationship to outcome are measured at baseline. For example, Alexander et al. (1989) describe how failure to obtain baseline measures of socioeconomic status in a community-based breast cancer screening trial led to severe problems of interpretation.

Although standard modelling procedures such as multiple linear regression (for continuous outcomes) and multiple logistic regression (for binary outcomes) will yield valid estimates of regression coefficients in the presence of clustering effects, their associated standard errors will be underestimated, possibly leading to spurious statistical significance. We now discuss extensions of these procedures that may be used to account for these effects.

The completely randomized and stratified designs

An approach that has now become standard for the control of either cluster-level or individual-level covariates in a completely randomized cluster randomized trial having a continuous outcome measure is mixed effects regression modelling, as discussed by Donner and Klar (2000, chapter 7). The term ‘mixed’ in this expression arises because the model contains terms representing the fixed effect of intervention as well as random effects representing cluster effects and random error terms. Also referred to as either a two-stage nested or a repeated measures analysis of variance model, it may be written as

$$Y_{ijl} = \mu + G_i + V_{ij} + e_{ijl}, \quad i = 1, 2; j = 1, 2, \dots, k; l = 1, 2, \dots, m_{ij} \quad (5.8.1)$$

The terms in this model include μ , the population mean response, and G_i , a constant representing the fixed effect of intervention group i ($i = 1, 2$). Two random effects are also included in the model. Random cluster effects, denoted by V_{ij} , are assumed to be normally distributed with mean 0 and variance σ_A^2 , that is, $V_{ij} \sim N(0, \sigma_A^2)$, while the remaining random error variation is modelled by assuming $e_{ijl} \sim N(0, \sigma_w^2)$.

The assumption that the cluster effects can be modelled as random variables implies that communities are theoretically obtained as a random sample from a well-defined population. This assumption is sometimes formally realized, as it was in the HIV prevention trial discussed in the section ‘The attraction of pair-matching as a design strategy’. However, structured sampling schemes in which communities are selected at random are often not realistic. Indeed, as discussed in the section ‘Ensuring the power is adequate’, they may be selected instead with the express purpose of reducing between-cluster variability. In this case, the generalizability of the results on a wider scale must rest largely on non-statistical factors, including judgement and past experience.

Maximum likelihood estimates of the intervention effect, adjusted for the influence of covariates, may be obtained in practice using the SAS® procedure PROC MIXED. Stratification effects representing factors such as cluster size and geographic area can be easily added to the model given by Equation 5.8.1 by suitably incorporating indicator variables.

A more complicated model is required if multiple outcome measurements are obtained after baseline and it is of interest to test if the time course of changes in the intervention communities differs from that in the control communities. Such an analysis may be of particular interest for examining the mechanism of action over time induced by an intervention. This approach was adopted by Resnicow et al. (2001), who evaluated a multicomponent intervention designed to increase fruit and vegetable consumption among African Americans as delivered through black churches.

Further discussion of such models, which require treatment-by-interaction terms to be added to Equation 5.8.1, is given by Koepsell et al. (1991).

For binary outcome measures, two main approaches tend to be used. The first is that of generalized estimating equations (GEE), developed by Liang and Zeger (1986), which leads to an extension of standard logistic regression that adjusts for clustering effects. The most common strategy used for this purpose is 'robust variance estimation,' which implies that random sources of variability are estimated using between-cluster information, yielding what is often called the 'sandwich' estimator of variance. An attractive feature of this strategy is that although the within-cluster correlation structure must be specified in advance (the 'working correlation matrix'), subsequent statistical inferences will be valid even if this correlation structure is misspecified. The most common working correlation structure specified for cluster randomization trials is 'exchangeable,' implying that the correlation between any two responses in the same cluster is identical.

As a consequence of this property, the validity of robust variance GEE is assured only if the number of clusters is fairly large. However, the minimum number of clusters required depends on many factors, including the cluster sizes and the number of covariates in the model, although research suggests that this figure ranges between 20 and 40 (e.g. Feng et al. 1996; Pan and Wall 2002). Although several small-sample adjustments to robust variance GEE have been proposed in the statistical literature (e.g. Mancl and DeRoune 2001; Pan and Wall 2002), further research is required to assess their effectiveness under a wide range of practical settings. Therefore, as discussed by Murray et al. (2004), this greatly hampers the application of GEE to all but the largest community-based intervention trials.

The use of a 'model-based' estimator of variance rather than a robust variance estimator will allow inferences using GEE to be valid in samples of much smaller size. This desirable property arises since the resulting standard errors are now based on an assumed within-cluster correlation structure rather than on between-cluster variation. However, it is clear that in a trial randomizing moderately sized communities, it would be very difficult to specify any particular correlation structure in advance, with the consequent risk of bias in the estimation of standard errors. Thus robust variance estimators, sometimes referred to as 'sandwich estimators', are much more widely applied than model-based estimators, in spite of their reduced efficiency and unreliability in small samples.

The GEE approach may be characterized as 'population-averaged' in that it measures the expected ('marginal') change in a response over all clusters as the value of the covariate increases by one unit. Thus the regression coefficient estimating the effect of intervention estimates the difference in the expected response for subjects

in the experimental communities as compared to subjects in the control communities, an interpretation similar to that for standard logistic regression. This is in contrast to an approach based on random effects or 'cluster-specific' models, which are characterized by the inclusion of parameters that are specific to each cluster, and which allows them to measure the expected change in response within a cluster as the value of a covariate increases by unit. Perhaps the most commonly used such model is the logistic-normal, which can be viewed as a standard logistic regression model with a normally distributed random effect. The interpretation of the resulting regression coefficients is then conditional on these effects. Unlike GEE, implementation of this procedure requires data that provides more than one observation per cluster.

Both population-averaged and random effects approaches can now be implemented using the SAS[®] procedures GENMOD and GLIMMIX, respectively, with analogous procedures available in Stata[®]. Although these approaches estimate the same population parameters when the outcome variable is normally distributed, this equivalence disappears in the case of a binary outcome variable, and thus their interpretation is different. As pointed out by Neuhaus (1992), interpretation of estimated covariate effects obtained from random effects models may be difficult when the covariate is defined at the cluster level, that is, takes on identical values within a cluster. This problem is most notable in cluster randomization trials, since the covariate of main interest tends to be the cluster-level intervention effect. Interpretation of such an effect using a cluster-specific model must formally rely on the notion of a subject within a given cluster changing his or her intervention status, clearly a non-observable event. This inability to provide internal validation has led Neuhaus (1992) to remark that random effects models are most suitable for testing the effect of covariates that vary within clusters (e.g. subject age or gender), while population-averaged models such as GEE are preferable for testing the effect of cluster-level covariates such as intervention status. However, it must also be noted that the differences between the two approaches disappear as the intraclass correlation coefficient approaches zero, and that more empirical work is needed to compare the advantages and disadvantages of the two approaches in practice. As pointed out by Omar and Thompson (2000), one advantage of the cluster-specific approach is that it provides direct estimates of variance components, and hence the intraclass correlation coefficient, quantities which are treated as nuisance parameters using the population-averaged approach. Moreover, it can also be extended to provide estimates of variance components at each of the multiple levels of clustering that arise in a natural hierarchy, such as villages selected from countries, or classrooms selected from schools that were in turn sampled from school districts. Some evidence also exists (e.g. Bellamy et al. 2000) that the logistic-modelling procedure performs better than GEE when the number of clusters is relatively small. However, the basic problem remains that clustering effects cannot be accurately estimated in this case, and thus the application of either approach to the adjustment of covariates in community-based intervention trials enrolling only a few communities is unfortunately limited in scope. An excellent non-technical discussion of the distinction between population-averaged and random effects models is given by Hanley et al. (2003).

The matched-pair design

A fairly simple but very general method that can be applied to incorporate the effect of covariates in a matched-pair design with a binary outcome variable has been described in the context of the COMMIT trial by Gail et al. (1992). The first step is to fit a multiple logistic regression model to the trial outcome data that contains the cluster-level and individual-level covariates of interest but which omits the variable representing intervention status. For each cluster the difference between the observed success rate and the expected success rate based on this 'null' model can be calculated by summing expectations over all individuals in the cluster. Then one can perform a paired *t*-test or one-sample permutation test on these residuals to test the null hypothesis of no intervention effect that takes into account the covariates at the first step. An analogous approach using multiple linear regression rather than multiple logistic regression may be used for the case of a continuous outcome variable.

While this approach may be used to control for the effect of both cluster-level and continuous-level covariates, it does not allow assessment of the independent effect of individual-level covariates on outcome. Such an assessment may be of interest when a secondary objective of the trial is to test the effect of covariates such as age or baseline blood pressure on outcome. Although aggregated versions of such covariates, such as mean baseline blood pressure, may be easily modelled at the cluster level using standard methods, modelling at the individual level may be of more direct interest. However, owing to the difficulty in estimating ρ this objective cannot be accomplished in a matched-pair design without making special assumptions.

One option available to investigators in this case is to break the matches and then perform a mixed model regression analysis as described in the section 'The completely randomized and stratified designs'. However, a theoretical objection to this strategy may be raised when both the outcome variable and the covariate(s) of interest vary with the remaining stratum effects, since the effect of such residual confounding may lead to an elevated type I error. Donner et al. (2007) have shown that this problem may indeed arise when a large number of small clusters are randomized. However, when a relatively small number of large clusters are randomized, as is the case in most community-based trials, the resulting test of significance for the independent effect of an individual-level covariate will in fact hold its significance level after the matches are broken. One caveat is that these results are restricted to the case of a continuous outcome variable and a single individual-level covariate, with the case of binary and multiple covariates requiring further research (Box 5.8.3).

Cohort versus cross-sectional designs

There has been considerable discussion in the literature as to the relative advantages of cohort versus cross-sectional designs for evaluating the effect of a community-based intervention. With the cohort approach, each individual is followed up over time, while for the cross-sectional design, different groups of individuals are independently sampled and assessed at each of several time periods. The former design is generally more powerful from a statistical perspective, since it permits an analysis that controls for individual baseline values, thus yielding a more precise estimate of the

Box 5.8.3 Common pitfalls in analysis

1. Indiscriminate use of relatively complicated multivariable methods without preliminary analysis of the data.
2. Application of generalized estimation equations or logistic-normal regression to trials enrolling fewer than 20 clusters.
3. Failure to recognize the relationship between mixed model regression and multilevel modelling.
4. Failure to appreciate the full efficiency of a cluster level analysis for a quantitative outcome variable when cluster sizes are equal.

intervention effect. This is not possible in cross-sectional designs, where covariate adjustment is restricted to cluster level summary measures. However, this theoretical advantage of a cohort design must be weighed against the risk of loss to follow-up that arises in any longitudinal study. If the loss to follow-up is different across intervention groups, the final estimate of intervention effect may be subject to substantial bias. Moreover, there may be substantial losses of efficiency relative to a cross-sectional design even when the subject attrition is unrelated to treatment assignment. Other disadvantages of the cohort design, as reviewed by Atienza and King (2002), include a loss of representativeness of the target population related to the ageing of the cohort, and 'learning effects' that may result from repeated assessments on the same individual.

From a conceptual perspective, the choice of design must also be considered in the light of how the primary question of scientific interest is posed. Thus if interest focuses mainly on change at the broader community level, cross-sectional designs may be the more natural choice while cohort designs may be more natural if change at the individual level is of most interest. Further discussion may be found in Feldman and McKinlay (1994).

Ethical issues in the design of community-based trials

Issues involving the need for informed consent

Guidelines for informed consent and other ethical issues are now well established for individually randomized clinical trials. Some of these guidelines apply to cluster randomized trials as well, such as the need for control group subjects to receive at least the current standard of local care and to be eligible to receive the new intervention on termination of the trial if it has been shown to be safe and effective. However, since the historical basis for such guidelines lies in the relationship between physician and patient, their direct application to cluster randomization trials, and community-based trials in particular, has proved to be controversial. As a result, ethical standards for such trials remain in the formative stage.

From this perspective, a distinctive feature of cluster randomized trials is that two levels of informed consent (and sometimes more) must be considered, one at the cluster level and one at the individual level. The first level of consent is generally provided by a key decision-maker such as a mayor or school principal on behalf of his/her constituents prior to randomization. In

relatively small trials it also may be possible to obtain informed consent at the individual level prior to randomization. However, in many trials recruitment must instead be done prospectively after randomization due to an inability to identify all eligible subjects prior to randomization. In this case the development of appropriate consent procedures will be more complicated, since it involves consent to be followed up under a treatment regimen that has already been assigned. Post-randomization consent not only raises difficult ethical issues, but also the possibility of selection bias as discussed in the section ‘Subsampling and the risk of selection bias’. Further complications arise when it is difficult or even impossible for a subject to withdraw from the study, as in the village-randomized trial described by Hutton (2001) that evaluated the efficacy of an insecticide spray.

Feasibility considerations alone will often present formidable obstacles to securing individual-level informed consent in community-based trials, as in trials that promote lifestyle changes through the media. In this case, where the intervention could be perceived as relatively benign, there may be little objection to the failure to secure informed consent at the individual level. Indeed the unawareness of the intervention programme on the part of community residents may in fact be perceived as a methodological strength of the study (Hutton 2001). However, more urgent challenges in securing informed consent may arise when relatively intrusive interventions are delivered, as in the case of trials delivering water fluoridation to all households in a community. In case of doubt, it seems reasonable to leave the decision to obtain informed consent to an independent committee, such as an Institutional Review Board (IRB). Unfortunately this solution may not always be straightforward, as most IRB guidelines do not distinguish clearly between consent at different levels.

A distinction made by Edwards et al. (1999) may be useful in clarifying these issues. These authors classify cluster randomization trials as either ‘cluster-cluster’ or as ‘individual-cluster’, depending on how the intervention is delivered. Thus in a cluster-cluster trial, the intervention is targeted at the entire community, as in the examples above, and it is difficult (although perhaps not impossible) for individuals to avoid. In this case, it may be argued that a ‘guardian’ or ‘gatekeeper’, such as a mayor or public health official, must not only provide permission for their cluster to be randomized, but should also sign a consent form clearly setting out the government’s duties for safeguarding its constituents’ interests. This approach can be seen to be consistent with guidelines for community-based research published by the World Health Organization and the Council for International Organizations of Medical Sciences (CIOMS 1993). However, other approaches have also been proposed, such as sampling the views of individual selected from the community (Eldridge et al. 2005). This approach might be particularly attractive when the decision-maker may not necessarily be a recipient of the intervention or may have special interest in the trial results (Hutton 2001). Further discussion of the role of gatekeepers in cluster randomization trials may be found in Gallo et al. (2012).

McRae et al. (2011) have set out a framework for addressing issues of informed consent in cluster randomized trials based on moral considerations and international regulatory provisions. They conclude that informed consent may not need to be secured if subjects cannot be approached at the time of randomization. However when potential subjects are approached after

randomization, ‘they must be provided with a detailed description of the interventions in the trial arm to which their clusters have been randomized; detailed information on interventions in other arms need not be provided’.

Cluster-cluster trials differ from individual-cluster trials in that for the latter it is possible to secure consent on an individual basis. As an example, a community-based prevention trial evaluating the effect of a new vaccine could allow any one individual the autonomy to accept or decline the intervention. Securing informed consent at the individual level should also be feasible in many health education trials and in trials administering supplementation by nutrients such as vitamin A, where the issues are very similar to those that arise in individually randomized trials. However for trials conducted in developing countries, it is recognized that procedures for securing such consent may vary somewhat depending on norms peculiar to the local setting (Hayes 1998).

The need for trial monitoring

It is largely ethical concerns that motivate the need for trial monitoring and interim analyses in individually randomized clinical trials. Thus data-dependent stopping plans, such as that proposed by O’Brien and Fleming (1979), have proved very helpful to researchers when termination of a study must be considered when one treatment shows unexpected early evidence of superior efficacy. The opportunity for early termination is particularly important for long-term trials having outcomes such as serious morbidity or mortality. However, it is interesting to note that cluster randomized trials in general, and community-based trials in particular, have not usually adopted formal procedures for trial monitoring. In some instances this may be due to the belief that unexpected early harm or benefit is unlikely given the nature of the interventions compared. Although this may be the case for some interventions, such as those designed to influence behavioural change, there are clearly many exceptions, as in long-term trials evaluating the effect of nutritional supplements such as vitamin A on child mortality.

A second reason for the failure to adopt formal stopping rules in cluster randomized trials is that the theory underlying the most frequently adopted plans has invariably assumed individual randomization. However, Zou et al. (2005) have recently shown that the most commonly adopted such plans may also be applied to cluster randomization trials with little difficulty. For trials that recruit communities prospectively, Lake et al. (2002) have also shown how an interim analysis of accumulating data can be used to re-estimate parameters such as the intracluster correlation coefficient, and hence ensure that the final trial power is of adequate size.

Reporting of results

Many of the reporting guidelines for community-based randomized trials are similar to those for cluster randomized trials in general, as discussed by Donner and Klar (2000, chapter 9) and by Campbell et al. (2004). A major contribution provided by the latter authors is an extension of the Consolidation of Standards for Reporting of Trials (CONSORT) Statement, developed over a decade ago as a template for reporting the results of individually randomized trials (Begg et al. 1996). A key element of CONSORT is a flow chart providing the number of subjects enrolled at each stage of randomization.

Some reporting guidelines have special relevance for community-based trials. For example, it was mentioned in the section ‘The completely randomized and stratified designs’ that the communities participating in a trial are rarely selected at random from a larger population of communities, with the risk of questions arising as to the likely generalizability of the conclusions (external validity). However, some understanding of this issue may be obtained by listing the number and characteristics of those communities that met the trial eligibility criteria but declined to participate. Similar reporting guidelines apply at the individual level if a subsampling strategy has been used to select residents within a community.

The interventions evaluated in many community-based trials are frequently complex, with many components. This has led to a debate in the literature as to whether it should be the ‘function and process’ of the intervention that should be standardized rather than its specific components, thus allowing flexibility in its tailoring to the prevailing local conditions (Hawe et al. 2004). However, in either case, it is incumbent on investigators to adequately describe the content of the intervention as it is actually delivered, whether administered directly to individual subjects or implemented solely at the community level. This again allows the reader to more easily generalize the results as well as facilitating its application by policymakers.

With respect to the randomization procedure, both the timing and the method used should be described in the context of the selected design. For stratified designs, the number of communities in each combination of intervention group and stratum should be reported.

The first table in a publication reporting the results of an individually randomized trial is usually a description of baseline characteristics in the two intervention groups. In cluster randomization trials, two such descriptions are required, one at the cluster level, for characteristics such as size, geographic location, and so on, and the other at the individual level, with emphasis in both cases on those characteristics likely to be related to outcome.

The use of significance tests for comparing baseline characteristics in individually randomized trials is now widely discouraged, since under a properly executed randomization scheme the source of any observed baseline difference cannot be other than chance (e.g. Senn 1994). The problem will be compounded in community-based trials if these tests are performed without adjustment for clustering effects, since then the obtained *p*-values will be spuriously low. In any case, it should be the magnitude of such differences rather than their statistical significance that should be used to decide if covariate adjustment is required.

If experimental contamination can be regarded as a potential source of bias, a description of the steps taken to minimize this problem can allow a reader to judge its likely impact. For example, Grosskurth et al. (1995) describe how data on place of residence was used to track patterns of migration across communities in the HIV prevention trial described in the section ‘The attraction of pair-matching as a design strategy’.

Differential loss to follow-up across intervention groups can be a threat to the internal validity of any trial. Therefore the reasons for such attrition, at both the cluster and individual level, should be provided. Reporting the overall individual loss to follow-up rate separately by cluster is also useful, since it allows the reader to

Box 5.8.4 Common pitfalls in reporting

1. Failure to describe the nature of the intervention in detail.
2. Failure to describe eligibility criteria at both the individual and cluster level.
3. Failure to present baseline characteristics by treatment group separately for individual level and cluster level characteristics.
4. Failure to report the observed value of the intracluster correlation coefficient or coefficient of variation.

understand if these losses are concentrated in communities having particular characteristics.

Since an assessment of between-cluster variation is crucial for sample size estimation, failure of investigators to report estimated values of the intracluster correlation coefficient handicaps the design of future trials in the same subject matter area. As mentioned in the section ‘Ensuring the power is adequate’, the magnitude of this problem has declined considerably over the last 15 years. However, a review of cluster randomization trials published from 1998 to 2002 indicates that there is still considerable room for improvement (Varnell et al. 2004).

Campbell et al. (2007) have reviewed the rapidly growing methodology available for handling clustering effects in both the sample size calculations and the analysis. Given the relative unfamiliarity of these methods, it is incumbent on authors to provide a clear statement of the procedures adopted, and, where appropriate, to provide accessible references (Box 5.8.4).

Conclusion

Despite the growing literature advising investigators on appropriate methodology, many community-based trials continue to be improperly designed and analysed. For example, failure to account for clustering effects at each of these stages can lead to serious problems of interpretation. Thus trials which fail to account for such effects in the assessment of sample size may fail to detect intervention effects having public health importance while those which fail to account for these effects in the analysis are prone to report spurious statistical significance.

We have also discussed issues related to the choice of design for studies randomizing intact communities, as well as the unique analytical and ethical issues that may emanate from this choice. More generally we have attempted to provide investigators with a better understanding of the many challenges involved in conducting a community-based trial and with guidelines for meeting these challenges.

Key points

- ◆ Clearly specify the unit of inference for the trial in terms of the stated objectives.
- ◆ Avoid the risk of selection bias if individuals are subsampled from communities.
- ◆ Be aware of the advantages and disadvantages of the completely randomized, pair-matched, and stratified designs.

- ◆ Ensure that the assessment of sample size and the approach to the statistical analysis adequately account for clustering effects.
- ◆ Use the CONSORT statement for cluster randomized trials as a guide to reporting trial results.

Community intervention trials in high-income countries

John W. Farquhar and Lawrence W. Green

Introduction to community intervention trials in high-income countries

As background on theories and methods underlying successful multilevel, multimethod, *community-based, health promotion intervention trials*, this chapter first reviews community organizational and mass media intervention developments in the first half of the twentieth century and the origin of randomized trials outside laboratory settings early in that century. It then reviews specific health examples from tuberculosis mobile X-ray and immunization campaigns in the 1950s and 1960s, family planning programmes in the 1960s and 1970s, and HIV/AIDS in the 1980s. We then turn to the most prominent and influential community health intervention trials for the remainder of the twentieth century as touchstones for development of twenty-first-century public health challenges, such as obesity and diabetes control, substance abuse prevention, and cancer control. These touchstones were the cardiovascular disease prevention and risk reduction trials (including most notably hypertension, tobacco, dyslipidaemia, and physical inactivity) mounted in California with the Stanford Three-Community Study and in North Karelia, Finland in 1972. Parallel national and statewide successes in hypertension control in the 1970s, and tobacco control in the 1980s and beyond, have drawn significantly on these and subsequent exemplary trials from North America, Europe, Australia, and elsewhere.

These later trials exemplify the scope and innovation of *experimental* epidemiology in advancing disease prevention and health promotion science, involving total populations of communities, initiated often following insights from *observational* epidemiology, or from *randomized clinical trials* in smaller populations. Some were derived from 'natural experiments' that studied the impact of policies and programmes not initiated by academic investigators.

The earliest of mid-century trials were often in developing countries, designed to reduce social development problems associated with communicable diseases and high birth rates. The communicable disease studies in Western countries gave opportunities to

test new polio vaccines and their adoption, and later by emergence of new infectious diseases, particularly HIV/AIDS. Other studies increasingly addressed risk factors for cardiovascular disease (CVD), cancer, and other chronic diseases as the rising mortality curve of chronic diseases crossed the declining curve of communicable diseases in the mid-twentieth century. All relied on locally available mass communication channels, community organizing, and other policy advocacy and educational methods, using relatively low-cost approaches with potentials to change lifestyles or specific behaviours.

One study examined alcohol-involved trauma using only community organizing to promote adherence to existing laws, rather than public education for policy-change advocacy (Holder et al. 1997). Another study, designed to reduce consumption of dietary trans fats, used primarily new laws and regulations (Angell et al. 2009). By community organizing we mean collaborating and seeking support from community leaders and other channels of communication. The World Health Organization characterized this as community participation or participatory planning (Green 1983), and as 'maximum feasible participation' (Moynihan 1969) for community projects under President Kennedy's 'New Frontier', and Lyndon Johnson's 'New Society' legislation. But this spin on community organization assumed lay communities set the goals (Green 1989). This orientation was recently termed 'community-based participatory research' when organizing was undertaken collaboratively at the initiative of the community or by academic or external health agencies (George et al. 1996; Minkler and Wallerstein 2008). Following further definition of community and community organizing for health, we review this history to identify some prominent precedents in the public health and community health promotion literature.

Definitions of community and community organizing for health

A community-based programme was defined historically as one organized locally, and promoted through the community's institutions and communication channels.

'Community-based' has become more broadly labelled, including both community-initiated and community-administered following initiation from external agencies. Programmes were termed 'community-placed' when conceived, sponsored by, or driven from organizations outside the community and applied with or without community participation.

The traditional definition of a 'community' is a residential area with legally defined geographic boundaries, where a *local* governmental system regulates many aspects of schools, businesses, law enforcement, transportation, and recreational activities. A community is usually the last designated jurisdiction in a nation's official or governmental regulatory chain, where education and implementation must ultimately occur. In rural areas the county or district becomes the agent for education and other official governance. For programmes funded by non-governmental organizations, local agencies or branch organizations are the implementing agents within communities.

The following summarizes changing precedents in effectiveness trials of community health promotion, reviewed by twentieth-century decades. It illustrates that technologies for solving emerging public health problems led to research in high-income countries, developing theories, and evidence needed for community interventions for large segments of the population at risk.

Some converging developments for community health trials

Table 5.9.1 summarizes a chronology of community trials that dominated eras of action research across seven decades of the twentieth century, and a few citations of works illustrating trial types and theoretical and epidemiological problems they tested, either as proof-of-concept trials, or as health promotion model evaluations.

The origin of randomized controlled trials (RCTs) is usually attributed to Sir Ronald Fisher (1925) for its application to field trials comparing effectiveness of alternative cultivation methods (Fisher 1926). Some rural sociologists began in the 1930s to study the spread among farmers of new hybrid seeds, providing technical assistance to farmers by agricultural extension agents. This led to the first publication of the diffusion model describing the normal-curve pattern of adoption of new ideas, behaviour, or innovations in populations (Ryan and Gross 1943). The diffusion model and its theoretical framing of social and behavioural change in populations has been chronicled by the rural sociologist Everett Rogers (2003), through five editions of his book, *Diffusion of Innovations*, and specifically for public health applications (Green et al. 2009). Rogers converged at Stanford with others who brought their various sociobehavioural and health disciplines to bear on development of the first large-scale, interdisciplinary US trial in community-based cardiovascular risk factor reduction. Table 5.9.1 recapitulates this history of community trials leading to and including the cardiovascular trials and beyond to tobacco control and now obesity control.

Tobacco control successes, from the 1960s through to the 1990s

Of all chronic disease prevention and health promotion efforts, tobacco control is the most cited as a great success of health

Table 5.9.1 Decades in which community trials of particular types dominated in development of a body of evidence, methods, and theories

Decade	Influential community trials	Examples and reviews
1930s	Agricultural extension trials and diffusion studies	Fisher 1926; Ryan and Gross 1943; Rogers 2003; Green et al. 2009
1940s	Mass media and war-years' propaganda studies; advertising, radio and film studies	Hovland 1948; Maccoby 1951; Michael and Maccoby 1953
1950s	Community mobile X-ray and various immunization studies	Hochbaum 1958; Rosenstock et al. 1959; World Health Organization 1954; Green 1970
1960s	Community family planning and polio immunization campaign trials	Stycos 1962, pp. 481–482; Berelson 1966; Bogue 1962; Northcutt et al. 1964; D'Onofrio 1966; Gray et al. 1966; Green et al. 1972
1970s	The first cardiovascular community risk-factor prevention trials	Farquhar et al. 1977; Puska et al. 1981
1980s	The HIV/AIDS and substance abuse prevention trials	Miller et al. 1990; Ruiz et al. 2000; Cain et al. 2001; Darrow et al. 2009; Kagan et al. 2012
1990s	Culmination of four decades of tobacco control	Centers for Disease Control and Prevention 1999; Rogers 2010; Levy et al. 2012
2000s	Obesity control	Institute of Medicine 2010a, 2010b, 2012a, 2012b

behaviour change on a population scale. Ironically, at least in North America, Europe, Australia, and New Zealand, this success, initially, was not the direct application of controlled trials, either clinical or community. It followed many planned media and educational events, popular media, policy initiatives and the environmental changes associated with them, and their evaluation through yearly measures of tobacco consumption. The mass media 'softened' public opinion, denormalizing smoking in public places, and assisting smoking cessation policy changes (Fig. 5.9.1).

These associations offer 'lessons' from tobacco control for chronic disease control at the population level, demonstrating that changing risk *conditions* in the social and physical environment is needed for behaviour change.

In addition to denormalization, research shows other policies and programmes have additive or multiplicative effects on reducing tobacco consumption and its premature mortality. The greatest impacts include tobacco price increases, high-intensity media campaigns, comprehensive cessation treatments, strong health warnings, stricter smoke-free air regulations, advertising bans, and youth access laws (e.g. Levy et al. 2012). Price increases have an independent effect; but the last three depend on both laws and their enforcement. These, in turn, have depended on building an informed and activated electorate through community-level organizing and communications, because community policies

Adult per capita cigarette consumption and major historical events—United States, 1900–2000

Fig. 5.9.1 Linkage in tobacco consumption trends with historical events in the social, economic, and policy environments.

Adapted from US Department of Health and Human Services, *Reducing Tobacco Use: A Report of the Surgeon General*, US Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Chronic Disease Prevention and Health Promotion, Office on Smoking and Health, Atlanta, Georgia, USA, 2000, available from http://www.cdc.gov/tobacco/data_statistics/sgr/2000/complete_report/pdfs/fullreport.pdf

controlling tobacco promotions and smoking in public places could be passed locally when they could not overcome industry lobbying at state and national levels.

Lessons drawn from the last seven decades of the twentieth century

We draw ‘lessons’ or generalizations for community prevention and health promotion interventions from seven decades of trials and natural experiments just reviewed, drawing especially on CVD trials and adoption and cessation trends of tobacco seen during the twentieth century (Fig. 5.9.1). Many ‘lessons’, derived from the tobacco consumption trends, were more readily adoptable within the CVD community trials, which began in the 1970s, and included smoking prevention and cessation. The tobacco experiences were also then seen as applicable to other risk behaviours at the community level. Finally lessons from these CVD trials lead to a description of the mix and sequence of the intervention steps needed.

The economic imperative

Cigarettes became increasingly popular and inexpensive in the century’s first three decades after manufacturing ‘advances’ reduced mass production costs, accounting for a steep rise in consumption. Consumption plummeted in the late 1920s during the Great Depression. This strong association in usage was early evidence for the wisdom of suppressing consumption through tobacco excise taxation. It demonstrated that even an addictive product is sensitive to price relative to disposable income. The argument for excise taxes gained momentum as evidence accumulated. A 10 per cent increase in cigarette price, on average, reduces consumption by about 4 per cent (Chaloupka et al. 2002),

and more for young, lower-income and pregnant smokers (Hyland et al. 2006).

Two other advantages spurred more cigarette tax initiatives. One is that revenues can finance statewide *and* community tobacco control programmes, making cigarette taxes even more palatable to the public, thus launching and sustaining some very successful programmes. The other is growing evidence that tobacco consumption increases healthcare expenditures, and since taxes decrease tobacco use, healthcare costs may eventually fall by billions of dollars in a state the size of California (Max et al. 2013).

The economic imperative also relates to obesity control and diabetes prevention, partly due to decades of increasing agricultural efficiency, causing progressive food price decreases. Food manufacturers and vendors have increased portion sizes, thus many have become accustomed to consuming larger portions and more frequent indulgences of cheaper, unhealthful food; much of it processed rather than home-cooked, and often with empty calories. These trends have led a contemporary movement advocating taxation of sugar-sweetened beverages (e.g. Novak and Brownell 2011).

The social normative or denormalization imperative

Two early notable changes in the trajectory of tobacco consumption were acceleration during the Second World War, and a less dramatic but significant rise during the First World War (Fig. 5.9.1). These are partly attributable to official condoning, facilitating, and even encouraging of smoking among soldiers to reduce boredom, and cope with stress, and smoking became integrated with their camaraderie. A modest drop in smoking occurs following the Second World War as soldiers’ social networks fragment. Later recognition of these social norm changes led to using mass media to portray smoking as less glamorous, less fashionable, less smart, and portrayed the tobacco industry as deceiving and

exploiting the public. Experiments within the community CVD trials began to highlight use of social influence strategies and media use to provide role models for changing behaviours, such as smoking (Ramirez et al. 1995).

The public health education and informed electorate imperative

Before mass media were used to create denormalization, most public health education was limited to smoking's health hazards, which had effects as noted. In 1954 a single mass media message created a precipitous drop in tobacco use. That year, *The Reader's Digest*, a popular and credible magazine with the American public, featured an article showing that tar of tobacco residues induced cancerous tumours when painted on mice. Although dramatic in its drop, consumption soon bounced back and continued upwards with continued tobacco industry advertising (Fig. 5.9.1).

As the public became more aware and cautious about tobacco, America was ready for the first Surgeon General's Report on Tobacco and Health in 1965, the peak of tobacco consumption growth. This and subsequent events led to legislation restraining the tobacco industry (e.g. the Fairness Doctrine requiring equal broadcast media time for anti-tobacco and pro-tobacco advertising). This indicated that public health education's most powerful method, certainly in relation to tobacco, was creation of an informed electorate—more supportive of regulations restraining industry advertising, promotion, and sales of a harmful product, and raising tobacco products' taxes.

The surveillance imperative

The tracking of tobacco consumption illustrates how helpful a consistently measured outcome or risk-factor metric related to particular chronic diseases can be. Ideally, such measures should be collected on whole populations and also on smaller subpopulations requiring particular attention. Regrettably, such surveillance—nearly universal for communicable diseases—remains sparse for most chronic disease risk factors. They are usually absent at the community level, so special surveys are needed for community intervention effects on behavioural and environmental issues. This expense alone makes trials prohibitively costly and dependent on a national government's funding.

The comprehensiveness imperative

The major tobacco consumption declines, following the first Surgeon General's Report on Smoking and Health in 1965, reflect the historical creation of national policies and programmes supportive of state and local efforts to create comprehensive programmes (Centers for Disease Control and Prevention 1999, 2007). Two states in particular (California and Massachusetts) in the late 1980s and early 1990s increased tobacco taxes, with a portion of the revenue earmarked for statewide and community tobacco control, including use of the social normative approach through schools, worksites, and mass media. These programmes achieved tobacco consumption reductions that doubled and then tripled decline rates of the other 48 states within a few years. Given results of these and later statewide and community trials, and success in measuring and tracking their effects, the Centers for Disease Control and Prevention's Office on Smoking and Health published in 1999 and updated in 2007 the 'Best Practices'

document cited earlier, guiding other states' comprehensive state-wide programme development.

The formative evaluation and tailoring imperative

Formative evaluation must begin before and be continued throughout implementation of any planned community intervention campaign. Success requires programmes well designed in mix and sequence, delivered through varied channels, adjusted for audience responses. This integration, with goals set in advance and adjustments from early results, is analogous to a commercial marketing campaign, hence the term 'social marketing'. (Ironically, *commercial* marketing has adopted many novel methods from academic research on *social* marketing.) It includes recognition of audience segmentation, or tailoring of messages and appeals to the varied motives, needs, and preferences of subpopulations (Slater and Flora 1991). Needs analysis, message design, and pre-testing are formative evaluation phases. Message sequences should first increase awareness, then knowledge, then motivation, and last provide training in the skills and resources to enable adoption and maintenance of new behaviours (Bandura 1986). Electronic media can furnish the first two parts of this sequence and stimulate use of more information-dense print media of newspapers, booklets, CDs, and websites, which are inherently more effective in *skills training* than are electronic media (Flora et al. 1997).

The ecological imperative

Health behaviours and health status are influenced by economic, political, cultural, and socioeconomic factors, all non-biological (Schooler et al. 1997; Best et al. 2003; Trickett et al. 2011). Healthcare's reliance on clinical services can neither prevent most chronic disease nor reach large population segments. Therefore, changing behaviour and improving health need to include family, cultural, and social contexts of these populations. A primary tenet of community prevention programmes is the opportunity to intervene in multiple settings and domains (Poland et al. 2000), and at multiple levels from individuals to families, organizations, and whole populations. This ecological approach honours the 'Comprehensiveness Imperative', but also urges communities to encompass interdependencies among environmental, social, and individual factors and the potential for public health strategies to interact with individually tailored therapeutic and medical strategies (Shea and Basch 1990; Schooler et al. 1997; Green et al. 2012; Farquhar in press). This principle is known as the ecological approach to community or population programmes (Green et al. 1996; Kok et al. 2008; Golden and Earp 2012), and has been a central tenet of the Ottawa Charter for Health Promotion (World Health Organization et al. 1986).

Community-based programmes offer opportunities to approximate the ideal multicomponent and multilevel approach by coordinating population-based policy and mass health communication and education strategies with individual-based clinical intervention. Social norms and community attributes greatly impact health. Community governmental and private institutions influence health behaviours by controlling, for example, health, recreational (e.g. Kokko et al. 2008), and transportation services (Mosquera et al. 2012) and youth access to tobacco. The health and safety policies and worksite health promotion practices of

businesses can also affect health. Stores and restaurants also shape health according to the food they sell (Schooler et al. 1997) and whether menus provide information on calories and ingredients.

The ideal programme design, then, would include programmes developed within or channelled through multiple and coordinated worksites, schools, recreation sites, libraries, churches, local business organizations, and other sites to supplement and expand the effects of policy and health education approaches and appropriate delivery of healthcare (Farquhar et al. 1985; Kokko et al. 2006; Dooris 2009). This broad reach into the community is critically appropriate to chronic disease prevention and injury control because most people are at some level of risk for these and will benefit from interventions to predispose, enable, and reinforce healthful behaviour, leading to creating a *population* impact on prevalent risk factors. Indeed, most CVD does not occur among the relatively few adults at highest risk, but among many at moderate risk (Blackburn 1979; Puska et al. 1985; Schooler et al. 1997). Therefore, population health promotion must reach a community's entire population, including those who are neither engaged with the health system nor motivated to reduce a possible distant development of chronic disease.

While some behaviour change reflects individuals recognizing and reducing a risk, a population-wide impact always requires diffusion of behaviour change from a social process—individuals learning about new behaviours from neighbours, or individuals being encouraged to adopt new behaviours by those in their social networks. Such social diffusion results best from increasing opportunities to learn about and implement new behaviours, plus increased social expectations for doing so. The tobacco control literature calls this the social norms approach, 'denormalizing', by making both tobacco smoking and the tobacco industry's practices socially unacceptable, an approach central to California's successful Tobacco Control Program (Rogers et al. 2010).

This social normative and total community approach requires building an environment that coherently and consistently favours behaviour change. In addition to policy changes and mass communications campaigns, this total environmental change may be aided by entrepreneurs recognizing a need and developing products to accelerate behaviour change, through workplaces providing incentives for adherence to wellness programmes (Volpp et al. 2009), through schools that modify food available to children and require physical activity (Lynagh et al. 1997; Michaud 2003; Loureiro 2004), through sports clubs (Kokko et al. 2006), and through programmes in other community settings. The goal is to create a behaviour change cascade, arising from synergistic interactive effects when many components are embedded in total community-based programmes that encourage institutional change, leaves space for entrepreneurs, and includes mass media and environmental change (Schooler et al. 1997).

Several synergies arise from combining multicomponent, multilevel (ecological) community intervention approaches with clinical services of physicians and other health professionals (Green et al. 2012). Adherence to dietary and exercise advice is more readily followed when family members, friends, and colleagues are modelling, enabling, and reinforcing these behaviours. Medication adherence improves when others in the patient's social network have learned, for example, about the need to control blood pressure and blood lipids. Health professionals, and their practice sites, potentially contribute to the 'total push' for better

health, for example, by supplying print materials on health and alerting their patients to forthcoming community health events.

Comprehensive community-based efforts may modify the environment to support healthful or inhibit unhealthful individual actions, create organizational and institutional support for programmes, and influence the knowledge, attitudes, and behaviours of individuals (Schooler et al. 1997). However, a pragmatic view on implementing community-based programmes includes healthy scepticism about depending on institutions if reducing the CVD burden is not central to their primary missions. For workplaces, schools, and other community organizations the advantages may be made more evident when improved health increases performance or reduces absenteeism, for example, of students or employees.

Committing limited resources from community-level organizations to programmes may be unsustainable if incentives are weak or if interventions are too complex to implement and maintain, leading to dissipation despite early enthusiasm (Thompson et al. 2000). For example, businesses that have insurance incentives to reduce smoking and obesity might invest in CVD prevention programmes, but few precedents exist for long-term sustainability and effectiveness even in high-income countries—and the potential incentives for businesses in low- and middle-income countries are less certain. However, recent findings suggest that financial incentives increase effectiveness of many worksite programmes, with evidence limited so far to their use in large worksites (Volpp et al. 2009). Similarly, physical activity is greatly needed in schools, but may not be implementable, given competition for limited educational resources and their primary academic mission. The infrastructure and capacity may be even more fragile in less formalized community organizations. More knowledge is needed on methods to create programmes and disseminate or scale them up in low- and middle-income countries.

'Best processes' to complement 'best practices'

Community intervention trials are typically funded to determine *efficacy*; multi-community trials test *effectiveness*, that is, what might result when applied to different populations with different community structures. The generalizability from these to many varieties of communities and populations involves external validity (Green et al. 2009). Adaptation is an assessment and planning *process* which considers the history, culture, demographic and political structure, attitudes, community needs, and diversity of a particular community.

Features of this planning, implementation, and evaluation process approach are shown procedurally in models such as PRECEDE-PROCEED (Green and Kreuter, 2004), which was informed by community trials following on Stanford and North Karelia, and the PATCH programme model of CDC (Green and Kreuter 1992).

Message characteristics

Messages must arouse interest in health improvement and disease prevention and appeal to individuals with varied backgrounds and knowledge. They must surmount indifference caused by the public's exposure to an *extreme* advertising overload. Since the 1990s, the average adult's annual exposure in the United States was 35,000 television advertisements, equalling 292 hours of

personal exposure (Fortmann et al. 1995). They must arouse interest and awareness and have production qualities able to capture the public's attention. Formative evaluation must continue to match message content to the population's readiness. Early campaign messages must raise awareness and increase knowledge; later messages should increase motivation, provide direction to access resources, and develop needed skills—with resultant behaviour change (Schooler et al. 1997).

For adolescents, for example, the following enhanced success: parents and teachers whose personal habits were role models; and amount and quality of school-based education on tobacco, fitness, and nutrition. Also, certain personal characteristics were influential—for example, the person's baseline *self-efficacy* toward one's behaviour-change abilities (Fortmann et al. 1995). Finally, as Perry, of the Minnesota Heart Health Project (Perry 2000) explained, if a peer-led smoking prevention curriculum reduced smoking onset among youth, effect preservation required other support: 'The careful links of behavioural curricula, parental involvement, community support and peer participation and leadership, with messages that are consistent and coordinated, have demonstrated efficacy beyond the implementation of a single strategy' (p. 122). This lesson is very germane for developing countries, given their proportionately high adolescent population.

The multiplicity and multilevel dimensions of community supports are shown in Table 5.9.2 as channels and mediators, referring to the individuals through whom the interventions can be personally or organizationally adopted and converted into reasons to act themselves, and then to influence others to change behaviour. They connect in the third column to the receiver's social cognitive change processes (Bandura 1986).

Prominent theories applied in community-based interventions

Community-based health education carried out by SPRC and some analogous projects has been guided by two major theories (community organizing and health communication–behaviour change), with success depending on their judicious blend (Flora et al. 1989; Farquhar et al. 1991).

Community organizing theory

This describes how to identify the community's health problem (and resources needed or available), and how to mobilize the

community's opinion leaders and organizations. It describes the need to form coalitions, begin and maintain educational programmes, achieve regulatory changes, and *empower communities* to reach and maintain their goals. See 'Functions (for the sender)' in Table 5.9.2. Community organizing has elements central to concepts of 'community self-development' (Green and Kreuter 2005; Minkler 2005) and includes elements of diffusion theory (Rogers 2003)—which has shown how innovations are adopted through natural social networks, aided by a community's opinion leaders. Rogers strongly advised to ensure that these leaders play an important role, given their perceived trustworthiness (Rogers 2003).

Health communication–behaviour change theory

Health communication–behaviour change theory describe the basis for educating the population and its subgroups considering their health needs, cultural attributes, social networks, media habits, attitudes, motivation, knowledge, and self-management skills (see Table 5.9.1). It describes principles underlying education's success, including social cognitive theory (Bandura 1986), which emphasizes an individual's capacity for self-directed change. Bandura's research builds on the long-standing educational principle that 'learning by doing' is more effective than 'learning from observing' (modelling a behaviour), and both are more effective than an 'information-only' approach. Bandura described these principles as *social cognitive theory*: proposing that guided practice in a new behaviour can increase self-efficacy and behaviour change beyond the usual (Bandura 1986). The health communication–behaviour change theory includes efficient ways to reach total populations using methods described earlier in this chapter as 'social marketing' (Kotler 1975; Lefebvre and Flora 1988). The goal of a comprehensive, multi-component, community-based intervention is to achieve 'community efficacy', just as 'self-efficacy' occurs for an individual after a successful behaviour change programme (Bandura 1986).

Specific methods for CVD community-based interventions

Problem identification

The first task is to identify the problem, initiated from within or outside the community. Local (community) interventions ideally interact with national programmes and link to scientific support

Table 5.9.2 The components of health communication–behaviour change

Communication inputs	Functions (for the sender)	Behaviour objectives (for the receiver)
Face-to-face messages	Determine receiver's needs	Become aware
Mediated messages	Gain attention (set the agenda)	Increase knowledge
Community events	Provide information	Increase motivation and interest
Environmental cues	Provide incentives	Take action, assess outcomes
Training for community sources of influence (parents, employers, etc.)	Provide training to enable and reinforce others	Maintain action, practise self-management skills
Diffusion and influence beyond the primary receivers	Provide cues to action, including environmental change	Become an opinion leader (exert peer-group influence)

Adapted from Farquhar, J.W. et al., Methods of communication to influence behavior, in Holland WW, Detels R, and Knox G (eds) *Oxford Textbook of Public Health*, Second Edition, Volume 2, Oxford University Press, Oxford, UK, Copyright © 1991, by permission of Oxford University Press.

from national or international levels, as noted with the family planning and HIV/AIDS histories. CVD prevention (World Health Organization 1986) and alcohol sales control (Holder and Wallack 1986) are problems requiring local action, and any chronic disease requiring widespread education for changing 'lifestyle' behaviours (such as exercise, diet, and cigarette use) will require analogous methods.

Formation of partnerships

Key opinion leaders as well as relevant organizations usually need to form a coalition or at least a network of strategic partnerships (Green et al. 2001) to assure coordinated agreement on needs assessments, planning and implementation, development of a community resource inventory, and mobilization of populace support for policy changes and enforcement. Relevant organizations, particularly in developed countries, include the following: the County Medical Society, or its equivalent, the local public health department, municipal hospital community affairs departments, city parks and recreation departments and voluntary health agencies (e.g. the local branches of national heart, lung, cancer and diabetes organizations). Any organization that will act as a conduit for the public's education should also be represented (e.g. television and radio stations, local newspapers, schools, churches, libraries, pharmacies, clinics, and physicians' and dentists' offices). As the coalition-partner numbers proliferate, a 'steering committee', preferably limited to six members, is needed for more detailed planning, including formation of expert groups ('task forces') in education and evaluation and other topics (Flora et al. 1989; Farquhar et al. 1991).

Matching for comparison

Assuming the high likelihood of a non-randomized or cluster-randomized small number of communities, and therefore a 'quasi-experimental' design (Flora et al. 1989; Mercer et al. 2007), successful implementation requires close matching of intervention communities (treatment) with comparison (control) communities on relevant demographic and socioenvironmental factors, while also minimizing shared media channels (Farquhar et al. 1985). Many community trials have not followed these important principles.

Intervention components

The goals include providing behaviour-change skills training, supplementing goals of increasing knowledge. They should enlist multiple sectors beyond health organizations in health improvement campaigns, including changes in social and built environments, and regulations that promote access to facilities and resources needed for healthful physical activity. Multiple communication channels can facilitate reaching subgroups with differing needs. Comprehensive interventions should involve schools, worksites, senior citizens' centres, churches, and facilities for sport, recreation, and health. Voluntary health agencies (such as the local branches of any national organization that deal with cardiovascular disease, diabetes, and cancer) should be involved. These can serve as education conduits, with the community's electronic and print mass media organizations assisting in message design, content, and delivery. The Internet's community education role (digital health) is now a major force (Baker et al. 2003) and can reach and benefit more than traditional channels—an emerging variant of mass media. Interactive computer learning, including

hand-held computers (King et al. 2008) ('mobile health') now provides new points of entry.

The intervention 'dose'

For future community intervention planning, an important question is how much amount and duration of intervention (the 'dose') is needed? Although outcome evaluations measure change achieved in health or disease risk, this 'dose' is rarely measured, thus cost-effectiveness remains a mystery. Dose measurement is difficult, the usual report gives only the intervention's duration and a cursory description of the educational inputs (Farquhar 2014), with little attention to reach or intensity (exposures). One can, at least, measure print and electronic media distributed, all converted to time, as was done uniquely in the Stanford Five City Project (Farquhar et al. 1990). Public health policy would be served if this were done more commonly.

The community transformative phase

This begins early in the community-organizing period, preceding the intervention, but accelerates throughout, particularly in the terminal period when external support diminishes or ceases (Farquhar et al. 1985). Enhancing a community's programme adoption for intervention sustenance is a major goal. This begins earlier, but becomes more definitive toward cessation of educational forces extrinsic to the community. A concurrent goal is to facilitate policy and regulatory changes that foster long-term goals and provide supportive physical infrastructures. The preferred outcome sees a continuing role for the original external academic advisors for community assistance, including the county's health agencies, to create new disease prevention programmes, as new technologies emerge. The ideal long-term outcome is that the 'transformed' community will advocate for local, regional, and national governmental regulations and laws increasing local intervention effects, such as smoke-free places, and extend them beyond the community.

The case of comprehensive community health promotion for CVD

The history of seven decades of twentieth-century community trials described has encompassed a mid-twentieth-century shift from public health and medical strategies appropriate to communicable diseases that accounted for the majority of deaths to those appropriate to a growing chronic disease burden. It outlined a series of formal research projects designed to affect health of communities, and illustrative CVD risk factors. The CVD trials have involved entire populations of at least one *education* community, compared to at least one *control* community. Three projects are described in greater detail here as case studies to provide examples of their methods and results. Dissemination worldwide into practical applications of community organizing and mass communication technologies, derived in part from these projects, occurred throughout these decades, with a relatively small number using research methods analogous to those described here.

Two examples: the first decade of CVD community-based projects

The first example is the Stanford Three-Community Study (3CS) in three small agricultural marketing towns in California (total population 45,000). The second is the North Karelia Study (NKS) in two adjoining predominately rural Finnish counties (North Karelia population about 180,000). Both projects began in 1972.

The first of two Stanford projects, 3CS, was carried out from 1972 to 1975 in both English and Spanish, comparing effects of 2 years of mass media plus ten-session risk reduction classes for 1 year for some high-risk adults in one community with the effects in a comparison community having 2 years of mass media alone, and a third as a control having neither (Farquhar et al. 1977; Schooler et al. 1997). Groups exposed to varied education amounts showed a dose–response change in levels of smoking, blood pressure, and blood cholesterol. Spanish-speaking residents had a proportionately larger effect than did the Anglo majority. A composite measure of CVD risk reduction at 2 years of about 23 per cent and 30 per cent occurred in the mass media-only and mass media-plus classroom conditions, respectively. The risk score (a probability) was derived from each adult's 'before–after' risk levels. These risk parameters predicted the 12-year future probability of a coronary heart disease event, using the scoring system derived from the long-term Framingham Heart Study (Truett et al. 1967). Thus, a relatively modest amount of mass media alone over 2 years (about 30 television and radio 'spots', weekly newspaper columns on heart health, and four separate mass mailings of booklets) was sufficient to change the population's coronary disease risk by 23 per cent. The education followed the principles outlined in the earlier section 'Prominent theories applied in community-based interventions' for prominent theories of community organizing and health communication-behaviour change.

In Finland, NKS evaluated two unmatched rural counties that contained many villages with farming and lumbering as their main occupations. North Karelia (which has a population of about 180,000, with the highest CVD rates in Finland) received an education campaign that began in 1972, continuing to the present and expanded to the entire country. After 10 years, CVD risk factor changes comparable to the 3CS occurred, and significant net reductions in CVD events occurred (Puska et al. 1985; Schooler et al. 1997). Extensive community organizing, resulting in strong partnerships with residents and their organizations marked this study. The NKS influence on Finland's national policies was unequalled among the CVD projects, giving its most important lesson—that a well-executed project led by respected scientists can change an entire country. Examples included Finland's food and agricultural industries making large changes: fertilizers were supplemented with selenium (a substance needed for health, but low in Finland's soil), milk pricing previously based on fat content converted to protein-based pricing, programmes were created to replace dairy farms with berry farms, a new canola industry replaced jobs lost in dairying, and increased production of low-saturated fat foods occurred (Puska et al. 1985, 1995). In 1972, population-wide nutrition change and smoking cessation interventions were an innovation internationally, which may partly explain the success of both 3CS and NKS (Green and Richard 1993).

Early international diffusion, 1977–1983

Building on the 3CS and NKS were studies carried out in various countries:

- ◆ Italy (The Martignacco Project, 1977–1983, one treatment, mass media and screening, one control—CHD risk fell in men only).
- ◆ Australia (The North Coast Project, 1978–1980, similar to 3CS, one mass media, one mass media plus classes—effects on smoking, greater in the mass media 'plus' community).

- ◆ Switzerland (two treatment, two control pairs, German and French speaking, with mass media, classes and environmental changes—small effects on smoking, blood pressure, and obesity).
- ◆ South Africa (similar to 3CS, one mass media, one mass media plus classes plus community events—decreased CHD risk, blood pressure, smoking; both treatments were equivalent).

All of these studies, reviewed in Schooler et al. (1997), reported significant risk factor changes, adding evidence both for the effectiveness of the 3CS model, and for the external validity of the evidence. In all, a predominately community-wide mass media campaign was effective, but a supplemental face-to-face instruction usually adds effects (Farquhar et al. 1991). A noteworthy qualification is that all these studies were done in rather small communities (population sizes of about 12,000 to 15,000 residents), thus achieving these effects may be more difficult in larger and more complex cities.

The second and third decades—projects begun in the 1980s and 1990s

The third case study, the Stanford Five-City Project (5CP) (California, United States), had an intervention phase of slightly more than 5 years, 1980–1986, and extended 3CS methods to larger populations (total population of about 360,000) with multifactor CVD prevention directed at two northern California cities, no intervention in three control cities (Farquhar et al. 1990). It differed from 3CS in larger community sizes, in greater use of community organizing, in greater collaboration with the communities' health, media and educational organizations in planning and implementing programmes, and in offering extensive continuing collaboration with Stanford. It was similar in its generous use of mass media, both print and electronic. The *proportion* of message sources received by the average adult over 5 years of education included: television and radio 67 per cent, newspaper 28 per cent, other print (such as booklets and 'tip' sheets) 4 per cent, and face-to-face 1 per cent. This dose measurement method, more fully described elsewhere (Farquhar 2014), was unique among all reported CVD community intervention programmes in measuring total education dose. In the intervention communities this amounted to about 5 hours/year and about 100 exposure episodes/year to all forms of media and classroom education (Flora et al. 1989; Farquhar et al. 1990). This method's use increased evaluation costs, almost two-thirds of total expenses. This expense may explain why others have not used it to similar degrees. Public health education would be served were more campaigns analysed in this way (Brown et al. 2012).

The first year of 5CP's television messages (characterized as 'high reach/low involvement') led to the public's later use of print media, which contained more specific instructions than from television in skills needed for changing smoking, diet, exercise, or weight control (Flora et al. 1997). Television, however, was also quite effective in skills training. For example, the 5CP presented an 8-week 'live' smoking cessation TV programme, demonstrating smoking cessation skills (Altman et al. 1987). The results of an antismoking campaign of a 'quit smoking' contest, the television and face-to-face classes, and a widely distributed print 'Quit Kit' were analysed separately. The highest cost-effectiveness was achieved by the low-cost print component (Altman et al. 1987). Results were comparable to the 3CS (about a 15 per cent fall in

Framingham composite risk of CVD) (Truett et al. 1967), with a major impact on blood pressure (4–5 per cent) and smoking (13 per cent) (Farquhar et al. 1990). The usually timid health policy experts might gain courage from the 5CP's evidence that only 3 hours/year of high-quality television health education can counteract the public's relatively intimidating exposure to about 100 hours/year of television advertising devoted to unhealthful nutrition. The US population's exposure is estimated as 292 hours of TV advertisement as measured by the Nielsen monitoring system (Farquhar 2014). Michael Jacobson, from the Center for Science in the Public Interest, identified that one-third of these promoted unhealthful nutrition (personal communication).

Compared to similar projects, 5CP's greater effects at relatively low cost, support that communication-behaviour change theory's predicted effects may be explained by mass media presentation components, including adaptation of skills training aspects of Bandura's social cognitive theory. An important lesson for policy-makers is that adult quitters saved over three times more money from their cessation of cigarette purchases (2860 quitters @ \$274/quitter/year) than the cost of the entire population-wide campaign (\$4/adult/year), which would justify cigarette taxes as the campaign's payment. Savings are retained life-long by the community's smoker-quitters, not counting long-term health costs' savings, and absenteeism from the individual's employment decreases, all accruing to the whole community. The intervention's relatively low cost is again emphasized, since the total yearly cost of cigarettes to the 22,000 smokers (over \$6 million) was 23 times greater than the yearly campaign costs (about \$260,000/year). Additionally, the county's Health Department adopted 5CP's technologies, applying them to seatbelt promotion, changing restaurants' saturated fat use, violence prevention, and adolescent pregnancy prevention.

More variably sized CVD projects occurred in the 1980s and 1990s in the United States, Sweden, Denmark, Canada, Germany, the Czech Republic, and China, including World Health Organization-sponsored projects (Schooler et al. 1997). The Minnesota Heart Health Project (MHHP) (Luepker et al. 1994) emerged as an important innovation source, pioneering introduction of antismoking contests (Lando et al. 1990), and demonstrating synergism in school health intervention effects when multiple schools in a community are involved within a comprehensive community intervention (Perry 2000). Many projects borrowed heavily from and often received training from either the Stanford or the North Karelia groups, although changes seen were often less than in those two projects. Reasons for lower success may defy explanations (e.g. the magnitude of the interventions was incompletely described). For many, the cause was likely due to inadequate use of inherently cost-effective mass media.

To summarize lessons learned, a five-step approach emerges from community trials, much derived from the Stanford 5CP, and some from various worldwide trials. Generalizability, of course, has limitations inherent in the nature of such trials, including designs, locales and methods:

1. Define the problem. Choose behaviour and environment change goals following community consultation.
2. Implement a 2-year campaign. Provide 3–5 hours of multichannel education/year. Year 1: 70 per cent electronic media, 15 per cent print, 15 per cent community classes, contests, health fairs. Year 2: change to 40 per cent, 35 per cent, and 25 per cent.

3. Evaluate. Use formative, process, and summative evaluations, tracking exposure, and effects of each intervention type. Use repeated cohort surveys to best measure effects, avoiding greater variance and in-migration's dilution effect. Repeated independent sample designs are feasible if in-migration dilution is less than 5 per cent/year.
4. Institutionalize. Continue intervention. Create a community demonstration project as a regional resource centre.
5. Leverage. Advocate for local, regional, and national governmental regulations to magnify intervention effects.

Conclusions

Six decades of applying the 'total community' health promotion approach in developed countries show unequivocally that considerable change is achievable at reasonable cost. Well-designed projects have transferred educational technologies and social-behavioural intervention skills to a community's infrastructure (public health, media, schools, etc.), resulting in significant improvements in health risk factors and conditions of populations (Schooler et al. 1997). Although many studies were done in small communities, recent successes in New York City (Angell et al. 2009), suggest that success occurs in large urban populations. Adherence to theory is key: gains in self-efficacy of many individuals through education results in *community efficacy*, enhancing changed institutional policy and practice, thus maintaining and extending community change. Changing communities through organizing and education requires *advocacy, activism, partnership building, and leadership*; success is enhanced by *regulatory change*. When needed laws and regulations come from state, provincial or national governments, local changes are enhanced. Both local and broad governmental approaches are needed to succeed in preventing chronic disease, which is particularly important for developing countries (Institute of Medicine 2010a). Adding well-planned, well-integrated digital health programmes, as yet untried, can likely increase effectiveness at decreased cost.

Community-based intervention trials in low- and middle-income countries

Sheena G. Sullivan and Zunyou Wu

Introduction to community-based intervention trials

In recent years, community-based intervention trials have been increasingly used to evaluate public health interventions to control disease and promote health. They can provide reliable data on the efficacy and cost-effectiveness of disease control strategies to inform policymakers in developing health policy and allocating resources. Typically, community-based interventions use lifestyle interventions that reflect community norms and are thus more readily integrated into current practices.

Community-based interventions were first used in high-income countries for reducing risk factors for cardiovascular and other chronic diseases. They began to be used in low- and middle-income countries in the late 1980s, initially to test programmes addressing maternal and child health. Early interventions targeted increasing immunization coverage (Desgrees du Lou et al. 1995; Brugha and Kevany 1996), decreasing general childhood mortality (Bang et al. 1990; Pandey et al. 1991; West et al. 1991), and maternal mortality (Fauveau et al. 1991), with a strong focus on reducing the impact of communicable diseases. More recently, the use of community-based intervention trials has increased considerably and the focus expanded to include non-communicable conditions, including cardiovascular disease (Dowse et al. 1995; Fang et al. 1999; Jafar et al. 2009), obesity (Kain et al. 2004; Li et al. 2008), mental health (Jacob et al. 2007; Pronyk et al. 2006), and cancer (Ramadas et al. 2003). These types of studies are now used to such an extent there are systematic reviews on specific types of community-based interventions in low- and middle-income countries (Lassi et al. 2010; Sguassero et al. 2012).

The results of these trials have been used in many cases to influence clinical and public health practice not only in the countries in which they are conducted, but also in other countries, including developed nations. For example, community-based sexually transmitted disease (STD) treatment trials in Uganda and Tanzania demonstrated that syndromic treatment of STDs could reduce the incidence of HIV infection at the early stage of an HIV/AIDS epidemic (Grosskurth et al. 1995; Wawer et al. 1998; Kamali et al. 2003), a strategy that was later recommended by the Joint United Nations Programme on HIV/AIDS (UNAIDS) and

adopted widely; a strategy to increase face-washing to reduce trachoma that was tested in Tanzania (West et al. 1995) and another to control fly populations in Gambia (Emerson et al. 1999) have since been incorporated into the World Health Organization's (WHO) SAFE strategy for trachoma control (surgery, antibiotics, facial cleanliness and environmental improvement), widely implemented in Africa (Ngondi et al. 2008).

In contrast, in some cases quality may be compromised to such an extent that the results cannot be used to influence health policy (Li et al. 2008). These trials are often complicated and expensive. Due to the scarcity of resources available in middle-income and particularly in low-income countries, community-based intervention trials have design and methodological features that may be different from similar studies in high-income countries. This chapter reviews community-based intervention trials in low- and middle-income countries. The chapter discusses study design, study population, intervention activities and quality of intervention, ethical issues, measurement issues, and interpretation and translation of results of community-based intervention trials conducted in low- and middle-income countries.

Design

Confusingly, community-based intervention trials can include a range of different study designs. Although the community, however defined, is the unit of intervention, evaluation may be done at either the community or individual level. Moreover, evaluation may be through cross-sectional survey or a cohort may be established, the choice of which has important implications for analysis.

Defining communities

Communities are generally classified along geographical or administrative lines, which in low- and middle-income countries is often a village, urban district, neighbourhood, census tract, or some other locally relevant administrative area. For example, in a study to examine the effect of vitamin A and β -carotene supplementation on postpartum illness in Nepal, randomization was by ward, a subunit of the study district consisting of several small subdistricts (Christian et al. 2000). Entire regions are also

sometimes randomized, as was done in four regions of southern Guatemala for a study evaluating the effectiveness of information, education, and communication strategies to increase maternal awareness about pregnancy (Perreira et al. 2002). Hospitals or hospital departments may also serve as the unit of intervention, as was done in a large, multicountry trial to evaluate a multidimensional approach for prevention of ventilator-associated pneumonia in intensive care unit patients of adult (Rosenthal et al. 2012b) and paediatric hospitals (Rosenthal et al. 2012a). For interventions among children, schools often provide a suitable environment in which to conduct intervention activities. In China, for example, there have been a number of attempts to conduct intervention trials to reduce overweight and obesity among schoolchildren, with the unit of intervention being either class groups within schools or entire schools (Li et al. 2008). The reality, of course, is that in many low- and middle-income settings, interventions targeting only schools or hospitals will miss a sizeable portion of the target population, most notably the very poor. However, targeting a comprehensive range of subcommunities is a strategy that has been used to overcome this problem, such as in a Vietnamese trial to control dengue vectors, where local leaders, health volunteer teachers, and schoolchildren were all targeted (Kay et al. 2002).

Regardless of what unit of ‘community’ is chosen, the unit should be well defined and variations within and between communities should be low. However, in reality this is often not the case. The size of the communities selected and factors that can potentially interfere with the outcomes often vary between selected study venues. It is important to understand the maximum tolerance of heterogeneity among selected study venues. The tolerance of venue variation should be based on appropriate statistical consideration.

Selection of study sites

The first stage of any study is to select an appropriate site for launching a trial. Several issues need to be considered. First, study sites must have a reasonably high prevalence of the events of interest, particularly sufficient high incidence. A high event rate is important to increase the cost-efficiency of the study and to reduce the duration of the trial. In low- and middle-income countries disease incidences are frequently high, particularly infectious diseases. Early community trials of STD treatment for HIV prevention in Africa were in part able to be conducted because of the very high rates of key STDs and HIV compared with other countries: in Mwanza, the average prevalence of syphilis was 15.6 per cent and the average prevalence of HIV was 4.1 per cent (Grosskurth et al. 1995); in Rakai, these figures were 10 per cent for syphilis and 15.9 per cent for HIV (Wawer et al. 1998); and in Mataka, they were 13.1 per cent and 9.8 per cent (Kamali et al. 2003).

Second, existing resources, when available, should be used as much as possible; otherwise the intervention will be expensive and will not be sustainable when the trial is completed. Traditional birth attendants have long been used in interventions to reduce neonatal mortality (Bang et al. 1990). In a community drug prevention study in China, schools, families, communities, and health service infrastructures were all used (Wu et al. 2002). A re-evaluation in 2007 indicated that intervention village residents continued to have higher HIV/AIDS knowledge than control village residents, and the villages were still using educational

programmes and cultural activity rooms established during the trial (Lee 2010).

Third, study sites should be representative of most communities affected by the diseases of interest. This is important because the intervention strategies and measures being tested in the trial should be expanded to other communities or even to the whole country or other countries if they are successful.

Fourth, study sites should be separated from each other in defined minimum distances in order to avoid contamination between intervention and control sites. However, given rapid economic and social development in low- and middle-income countries, people move from one place to another frequently. It is also true that the Internet has created a way for people to communicate almost with no boundaries. These factors should be considered in the study design stage.

Understanding the setting

Prior to attempting any kind of study, it is important to understand the community’s dynamics, administrative structures, cultural characteristics, and existing infrastructure. In some settings, census information or public records may be available, although they may be out of date (Eder et al. 2012). Usually little background information about study communities is available in low- and middle-income countries.

Qualitative methods are effective tools for collecting the necessary background information to develop a suitable intervention. It is important to interview key informants in the community. Key informants include community administrative leaders, community religious leaders, opinion leaders, and, importantly, members of the target community. Information can also be sought from these people through focus group discussion. Wacira et al. (2007), in designing an intervention to increase the use of insecticide-treated bednets in Kenya, conducted interviews and focus group discussions with representatives from government ministries, companies, and non-governmental organizations as well as employers and community members. Bhandari et al. (2003), in designing an intervention to improve perinatal and neonatal health outcomes, used qualitative methods to collect information about community characteristics, children’s nutritional status, feeding practices, and reasons children may not be breastfed.

On-site observation can also be used to understand community dynamics. This method was used in the National Institute of Mental Health (NIMH) Collaborative HIV/STD Prevention Trial study in five countries (NIMH Collaborative HIV/STD Prevention Trial Group 2007a). Anthropologists observed daily activity in food markets from 6 a.m. when the markets opened until 6 p.m. when they closed. Their major objectives were to identify the most influential individuals within the markets who could be selected and trained for delivery of the intervention and to identify existing social networks among food market vendors that could be used for diffusion of the intervention.

For interventions which target specific groups or venues, researchers may also use mapping tools to identify where and when target groups congregate. An intervention to promote condom use among Lao *Kathoy*, for example, first mapped all the venues where they congregated and the peak periods of activity to develop their sampling framework for administering evaluation questionnaires (Longfield et al. 2011).

The amount of effort that should be put into a qualitative study prior to a trial varies from study to study and depends on how complex the proposed intervention is, how complex the communities involved in the trial are, how much background information already exists, the prior experience of the investigators, and how much money is available for the study.

Community consultation

Complementing the qualitative study should be a comprehensive consultation with the community. Different communities include different subgroups of people, each with its own characteristics, interests, and needs. Comprehensive consultation with different subgroups is an important part of project planning and design that can influence whether or not a project is in fact successful. In a review of 12 community-based intervention studies, 11 reported that community involvement had enhanced the quality of the intervention; two thought that it had improved the outcomes; eight believed it had improved enrolment; four noted better research methods and dissemination; and three described better descriptive measures (Agency for Healthcare Research and Quality 2003). Those members of the community who are consulted may include any person or organization relevant to the trial. For example, a drug prevention study in China consulted a wide range of people, including government leaders in education, health, public security, culture and entertainment, agriculture technology, ethnics group management, and poverty alleviation, as well as community leaders, youth leaders, women leaders, student leaders, teachers, village health workers, and drug users (Wu et al. 2002). Multisite interventions may choose to consult different community members in the different sites.

Ethical concerns with the conduct of research in low- and middle-income countries have led to calls that studies organize a formal community advisory board (CAB), which is consulted to ensure communities are not exploited (Emanuel et al. 2004). Their role extends to include: providing community support for a trial; identifying priority health concerns; assessing the value of research; planning, conducting, and overseeing the research; integrating the results into the healthcare system; respecting the community's values, culture, and social practices; and ensuring that communities benefit from the research (Emanuel et al. 2004). There is no clear consensus on the composition of a CAB, but specific funding bodies or trial groups may have their own requirements. The AIDS Clinical Trials Groups, for example, requires CABs to include people infected with HIV and trial participants and suggests inclusion of patient advocates, parents, community-based healthcare providers, religious leaders, and representatives of underserved communities (AIDS Clinical Trials Group 2012). Even with guidelines, the CAB elected may be ineffective. For example, in Tanzania, initial efforts to establish a CAB for a site for malaria drug and vaccine trials as well as tuberculosis and HIV research met with many problems: village leaders who were asked to recommend individuals to represent their village elected themselves, leading to an overly-male CAB—entirely inappropriate for studies largely targeting women and children—whose attendance was very low, thus compromising training requirements and the establishment of easily-recognized CAB representatives, and who hindered study coordination because of their own political interests (Shubis et al. 2009). While CABs in high-income countries were often developed by activists and

researchers who demanded their involvement in research, in low- and middle-income countries CABs are manned by community representatives who are asked to become involved and who therefore may have different expectations, including monetary expectations (Shubis et al. 2009). Efforts to instil a sense of empowerment can help CAB members to perceive that they are respected by the investigators, that they share the ownership of the project, and, therefore, that they share the responsibility for the success of the project. It is important to promote the perception that the project is the community's project, that it will benefit the community, and that everyone has a responsibility to participate.

The comparison group

Community-based intervention trials typically follow one of two formats: (1) an intervention/control or intervention/intervention comparison or (2) a pre-/post-intervention comparison. The simplest approach is the latter; that is, to compare baseline prevalence of a disease or behaviour with the prevalence post intervention. In some situations, this may be the best option available. For example, in 1987, the Senegal government introduced immunization programmes into Bandafassi, an isolated area that previously had had no regular immunization programmes. Since regular immunizations were the only change introduced into the area during this period, it was possible to assess the impact of immunization on childhood mortality by comparing mortality rates before and after the immunization programme was introduced (Desgrees du Lou et al. 1995). In a study promoting consistent condom use among female sex workers in China, high mobility among the sex workers precluded the researchers' ability to identify a suitable control group (Wu et al. 2007). Sex workers would frequently work in several establishments at the same time or quickly move between establishments. Those sex workers coming from an intervention establishment to a control establishment who shared their new knowledge with co-workers would dilute the intervention effect and could incorrectly lead to the conclusion that condom promotion had had no effect, a process known as contamination. Studies that use the mass media are particularly affected by contamination and necessitate a pre-/post-intervention comparison. In Burkina Faso, an intervention to distribute drugs against schistosomiasis was preceded by a nationwide information campaign utilizing television and radio to ensure high compliance with the treatment, eliminating any possibility of using a control group (Gabielli et al. 2006).

A more robust design is to have a control group; a group which was comparable with the intervention group at baseline and who, for the duration of the intervention, experienced none of the intervention activities, but did experience other phenomena which may have led to an improvement in the desired outcome anyway. This last point is impossible to control in pre-/post-intervention comparisons. Intervention and control communities may be assigned, as in a quasi-experimental design, or may be randomly allocated, as in a cluster-randomized controlled design (discussed further in the next section).

Studies do not have to be limited to testing one intervention against a control. Multiple interventions can be tested and compared with controls to determine which combination of activities leads to the greatest impact. In Honduras, a programme to increase the use of healthcare services compared four groups: (1) money given directly to households, (2) resources to local health teams

combined with a community-based nutrition intervention, (3) both packages, and (4) neither package (Morris et al. 2004). In some cases it may be deemed unethical or impractical to have a control group, in which case it may be possible to compare two different interventions. In the study of trachoma in Tanzania, intervention villages received free treatment and health education while 'control' villages received the treatment only (West et al. 1995). The addition of health education carried an additional cost but the study showed it would be worth implementing on a wider scale since children in intervention communities were 60 per cent less likely to develop trachoma. Alternatively, the design may include a wait-listed control, where the control communities receive the intervention once it has been shown to be effective. This was done in a programme that combined microfinance and gender/HIV training in South Africa (Pronyk et al. 2006). Communities were pair-matched, then randomized to receive the intervention at study onset or 3 years later.

Randomization, matching, and stratification

Well-designed randomized controlled trials are recognized as the gold standard for the evaluation of public health interventions. With randomization, unmeasured confounding factors are expected to be equally distributed in the intervention and comparison groups. Unbiased effect-estimates and valid confidence intervals can therefore, in theory, be obtained. The extension of this in community-based trials is to randomize at the community level, following the cluster- or group-randomized trial design, where the unit of randomization is the community rather than the individual. The number of units of randomization in community-randomized trials is usually smaller than in individually randomized trials, although the number of individuals may be large. In Nepal, studies to improve postpartum outcomes randomized 270 wards in 30 villages to one of two intervention groups or a control but the total number of individuals enrolled in the study was more than 15,000 (Christian et al. 2000). Often, community trials have fewer communities available for randomization. When the number of units is very small, randomization is less likely to achieve comparability between intervention and control groups at baseline.

To overcome dissimilarity between intervention and control communities, researchers may consider matching, which involves matching communities on factors highly associated with the outcome variable, and then randomizing within the matched pair. For example, in the study of the effect of face-washing on trachoma, three paired villages were matched on the level of maternal education, baseline prevalence of clean faces in young children, and trachoma status. Within each pair, one village was randomized to the intervention and the other to the control group (West et al. 1995). The rationale for matching is to improve power in randomized studies. However, if matching variables are not strongly associated with the outcome, matching actually reduces study power through loss of degrees of freedom with a small number of experimental units (Martin et al. 1993).

An alternative to matching is stratification, where communities may be grouped rather than paired by variables associated with the outcome and later randomized within strata. In both matching and stratification, the degrees of freedom are reduced, but this can be offset by the decrease in the variance between communities, which in turn can reduce the design effect and improve power. The results of

the three landmark STD/HIV community-randomized trials conducted in Africa (Grosskurth et al. 1995; Wawer et al. 1998; Kamali et al. 2003) were compared to examine the differential effects of stratification or matching (Todd et al. 2003). In Mwanza (Grosskurth et al. 1995) and Masaka (Kamali et al. 2003), matching and stratification reduced between-community variance and improved the power of the study compared with an unmatched or unstratified design. In the Rakai trial (Wawer et al. 1998), where communities had been selected to be relatively homogeneous, matching reduced the variance between communities but did not increase power.

In certain circumstances, randomization of intervention units may not be possible. This may occur, for example, when study villages are adjacent to one another and the risk of contamination is high. In a community-based intervention trial to reduce childhood mortality from pneumonia, random allocation was not performed (Bang et al. 1990). The intervention included mass education about childhood pneumonia and case management of pneumonia by village health workers and traditional birth attendants. A total of 102 villages in one contiguous area were studied, of which 58 villages were assigned to the intervention group and 44 villages were in the control group. The two groups were separated by a small 'buffer' zone of a few villages. In this example, given the geographic proximity of the intervention and control communities and the use of mass education, the other choices available to the researchers were randomization without using mass education, or using the mass media without a control area.

Where randomization is chosen, investigators should follow the guidelines found in the CONSORT (Consolidated Standards of Reporting Trials) statement (Campbell et al. 2004). This statement was initially designed to guide the reporting of randomized clinical trials and has since been updated to provide guidance on the reporting of cluster-randomized trials. It includes a flow diagram and a 22-point checklist to remind researchers to include important information necessary for objective interpretation of the results, such as the intracluster correlation, design effect, and power and sample size calculations. Many medical journals now require adherence to the statement as a condition for publication.

Cohort versus repeated cross-sectional samples

Whether a study design uses a pre/post or intervention/control design, measuring the effect of the intervention is usually done at the individual level. Ideally, all individuals in the target population are sampled. Two early studies to reduce childhood mortality in India (Bang et al. 1990) and Nepal (Pandey et al. 1991) were able to carry out a census of all children under 5 years at the beginning of the study and enumerate all births and deaths during the study. However, conducting a census is expensive and often not logistically possible. Thus, researchers in low- and middle-income countries have generally needed to make a choice between one of two study designs: (1) a cohort study design, where a selected group of individuals is followed up for changes over the course of the study; or (2) a repeated (serial) cross-sectional survey design where different groups, usually randomly selected, are assessed at each time period. This decision depends on the characteristics of the outcome variable, the information-collecting system available at the study sites, the ability to follow the sample population, and the amount of funds available for the study.

Cohort studies are statistically more powerful than cross-sectional surveys, since individual baseline characteristics

can be controlled, which reduces sampling error. Moreover, the change in disease frequency or knowledge, attitudes, and beliefs can be compared both between intervention and control and pre/post intervention. For example, the Chilean intervention to prevent childhood obesity enrolled children at intervention and control schools, measured various adiposity indices at baseline and again at 6-month follow-up, and was able to measure the *relative* changes between intervention and control schools over the 6-month study period (Kain et al. 2004). Sometimes results based solely on a cohort may not be representative of the target population due to selection bias. The cohort sample is often a self-selected subset of that group who are willing to be followed up. Attrition throughout the study may also decrease the external validity of the sample, particularly if the participants who leave the study are disproportionately reached by the intervention. Moreover, repeated measurement may act as a kind of intervention in itself, increasing participants' knowledge and confounding the results.

Cross-sectional studies also have their own strengths and weaknesses. Given that the target population for community-based interventions is often the wider community, it could be argued that cross-sectional surveys are more appropriate to see changes in the communities targeted. They may include people who have had extensive or limited exposure to the intervention, thus giving a more representative picture of the intervention's reach. On the other hand, this may also be seen as a weakness, especially when limited exposure is associated with in-migration and a related short duration of exposure, rather than limited reach (Feldman and McKinlay 1994). Cross-sectional surveys are often used to assess mass-media campaigns, since it may be impossible to find an unexposed control group. In a systematic review of 24 media campaigns to change HIV/AIDS-related behaviours in developing countries, 15 used cross-sectional surveys to measure the impact of the campaign (Bertrand et al. 2006). There are other circumstances where cohorts are almost impossible to establish, such as in areas of high migration. In the trial to promote condom use among sex workers in China, repeated cross-sectional surveys were the only feasible choice given the high turnover of sex workers in the study site (Wu et al. 2007).

Sometimes a retrospective cohort can be reconstructed in repeated cross-sectional surveys. In the study of prevention of drug use in China (Wu et al. 2002), the incidence of drug use among adolescents and young adults was estimated based on a reconstructed retrospective cohort derived from repeated cross-sectional surveys. This was possible because there was very little migration in or out of the villages and the village leader was responsible for recording all in- and out-migrations.

In some cases, both a cohort and a cross-sectional survey have been used simultaneously. In China, an intervention to improve the quality of life of people living with HIV that comprised both an intervention for patients and a popular-opinion model targeting the community enrolled a cohort of people with HIV among whom changes in perceived and felt stigma could be measured, and conducted serial cross-sectional surveys of the community to assess the impact of the community campaign to reduce stigma towards people living with HIV (Xu et al. 2008).

Sample size and statistical power

The estimation of sample size in any study depends on the availability of background information on the prevalence of the disease

or behaviour of interest, the size of the source population, and the likely refusal rate. This can be achieved through reviewing data available from similar studies in the target group. For example, a study to prevent childhood obesity in Chile used average body mass index values from an earlier survey of nutrition and obesity in Chilean schoolchildren (Kain et al. 2004). Alternatively, census data may be available, although this can sometimes be out of date. A group re-evaluating an intervention in Bolivia, for example, discovered too late that the census data they had used to develop their sampling frame did not reflect the real number of households in each village, resulting in recruitment of 73 per cent of the intended number of households (Eder et al. 2012). National estimates may also be used, such as those for neonatal mortality and birth rates, which were used to determine sample size in a Nepali study of a participatory intervention to reduce neonatal mortality (Manandhar et al. 2004).

The method used to estimate sample size is of course dependent on the study design. In the community intervention trials discussed in this chapter, the designs varied: the number of communities involved ranged from one (self-controls) to a comparison of two communities to a comparison of many communities either assigned or randomized to receive the intervention(s) or control condition. For example, in the Mauritius non-communicable disease prevention study, it was not feasible to use a control area in the small island, therefore only one unit was used, assessed by pre- and post-intervention cross-sectional surveys including 5080 and 5162 participants, respectively (Dowse et al. 1995). Emerson et al. (1999) used two pairs of villages (1124 children enrolled at baseline) to study control of trachoma and diarrhoea in Gambia. In such non-randomized studies, the sample calculation is straightforward and estimates the number of community members to be recruited. However, when multiple communities are used there are other parameters to consider, and methods for cluster-randomization should be employed. Individuals within a community are more similar to each other than to individuals from another community and are therefore more likely to have the same outcome. This violates the assumption of independence between observations, which is essential in most statistical analyses. Thus, the correlation between individuals within communities can greatly affect the sample size (Kerry and Bland 1998a). For example, a study which has enrolled 2000 people in 50 clusters may note that individuals within those clusters are all very similar in terms of key covariates, so the effective sample size is actually closer to 50 than it is to 2000. The sum of the variance between subjects in a cluster and the variance between clusters, is used to calculate the intracluster correlation and is used to calculate the design effect (Kerry and Bland 1998b). This is the ratio of the total number of subjects required using cluster randomization to the number that would be required if individual randomization were used. It is used to estimate how much larger the sample size (of individuals) needs to be to achieve statistical power. For example, if the design effect is 1.17, then the number of participants needs to be increased by 17 per cent (Todd et al. 2003). In estimating the required sample size these parameters need to be known a priori and can be estimated from previous studies or existing data on the study communities. However, such information is often unavailable or incompletely described (Kerry and Bland 1998a).

To a certain extent, increasing the number of individual observations in a cluster can reduce the variability within communities

and increase statistical power, but at a certain point this effect plateaus and the number of clusters needs to be increased. In general, if communities are particularly homogeneous, a larger number of small communities should be considered. However, the advantages of increasing the number of communities needs to be balanced with the feasibility and costs associated with targeting more communities. In the South African study to reduce intimate-partner violence, the number of clusters was limited to four in each study arm because of operational constraints, including the time required for recruitment and follow-up, the need to enrol all households in a village before expansion, and ethical concerns about withholding the intervention from control villages (Pronyk et al. 2006). Conversely, a smaller number of communities can be used if communities are relatively heterogeneous. In either case, the number of individuals required in cluster-randomization is larger than would be needed for individual randomization and failure to do so comes at the expense of power to detect a difference between groups. For example, in a study to promote exclusive breastfeeding in Mexico City, 39 clusters with two to four city blocks each were randomized to one of two intervention conditions or a control. A total of 125 children were enrolled in each arm, which met the minimum required sample size of 120, based on $\alpha = 0.05$ (one-sided), and giving 86 per cent power to detect a 20 per cent absolute difference in exclusive breastfeeding between intervention and control groups (24 per cent versus 4 per cent) if there was no design effect; accounting for a design effect of 1.2, power was reduced to 76 per cent (Morrow et al. 1999).

An alternative to increasing the sample size in an individual study or site is to pool data from different trials or run multisite trials. Pooling data from trials that were not planned together requires they have comparable outcome measures and can be difficult to achieve. Even multisite trials may find it difficult to preserve the study design. The NIMH Collaborative HIV/STD Prevention Trial is a community-level study conducted in five countries—China, India, Peru, Russia, and Zimbabwe—to assess the efficacy of an intervention involving popular-opinion leaders to reduce the incidence of HIV/STDs (NIMH Collaborative HIV/STD Prevention Trial Group 2007b, 2010). The trial used comparable intervention strategies and data collection instruments to allow the pooling of data to increase power, although individual sites were also powered to observe an effect. Site-specific sources of variance need to be taken into account when determining sample size and power and in analysing the results.

Further discussion on sample size calculations for cluster randomized trials can be found in Chapter 5.8.

Ethical issues

There are several ethical issues unique to community-based interventions, some of which can affect the study design. Foremost is the issue of informed consent. Obtaining informed consent from every individual in a target community to be exposed to an intervention is often impractical and can compromise the validity of the trial by artificially raising awareness of the problem being addressed. Moreover, individuals may not be able to realistically avoid exposure to an intervention, such as when the mass media is used to deliver the intervention (Sim and Dawson 2012). Community consultation with different stakeholders and approval from a CAB may be seen by some as seeking the consent

of the community to conduct a trial (Edwards et al. 1999), while others believe that an internal review board's review should be sufficient (Sim and Dawson 2012).

Where individuals in a community are enrolled in a cohort to receive specific intervention components, consent can be sought from those individuals. However, unlike a drug trial, which can be double-blinded and where participants are aware that they may receive treatment or placebo, community trials often involve educational or other programmes and participants know whether they are receiving the intervention or not. By fully informing participants in the control group about the intervention during the informed consent process, contamination may be introduced by prompting the controls to seek out the information that their counterparts in the intervention group are receiving. Contamination can be reduced by using geographically distant communities, but this may lead to incomparability between comparison groups. If controls are receiving routine care, then it may be considered acceptable to withhold information regarding the intervention from them. In this way, individual consent to participate in intervention activities is sought only from those in the intervention communities, and consent for data collection and to be contacted for follow-up is taken from all parties (Edwards et al. 1999). There is a balance between ensuring study validity and protecting participants; contamination could reduce the efficacy of a trial, and conducting a methodologically-poor study may be perceived as being unethical (Sim and Dawson 2012).

The problem of whether to fully inform controls about the intervention is further complicated when monetary incentives are introduced. In many low- and middle-income countries, financial or other incentives, such as free food, washing powder, or other household consumables, are provided for participation in a trial. Any financial or other incentive may be viewed as coercion given the poor financial situation of most eligible participants in low- and middle-income countries, but in many of these settings incentives are expected. The nature and amount of such incentives should be described in the study protocols submitted to ethics review committees, which will ultimately decide if the incentive implicates voluntary participation. Where controls are concerned, fairness and justice may be compromised. Both intervention and control participants would normally receive reimbursement for data collection activities, but controls would not normally participate in any intervention activities, such as skills training, so would not be eligible for any associated reimbursements. In addition, there is some risk that incentives increase the intervention effect by creating a motivation to participate that artificially increases exposure.

In some instances it may be unethical to even have a control group at all, such as when an intervention is already known to be effective. Instead, two interventions may be compared, a wait-listed control used, or researchers may need to consider a pre-/post-intervention comparison within intervention communities only. In some low- and middle-income countries, communities do not understand the need for controls, or believe them not to be cost-effective because of the expenses involved in maintaining such communities. Similarly, they may not accept the process of randomization. In these situations it is important to educate the government or communities about the need for controls and randomization in yielding scientifically valid findings, and alternative study designs may need to be considered.

As researchers from high-income countries intensify their research activity in low- and middle-income countries, and as researchers from low- and middle-income countries increasingly bid for foreign funding, adherence to international ethical guidelines has become increasingly important. This includes the establishment of institutional structures, such as institutional review boards (IRBs) or ethics committees that can monitor the progress of the research and protect the people enrolled in the trials. International Guidelines for Epidemiological Studies (CIOMS 2009) have been developed to help guide these institutional bodies. But questions may remain (Weijer et al. 2011). For example, would an IRB in a developing country really understand the ethical issues posed by a study for a community in a low-income setting and be able to assess the appropriateness of informed consent procedures? Conversely, would an IRB in a developed country have sufficient, well-trained epidemiologists to assess the methodological quality of a trial? Where interventions have been successful in developed countries, their translation to low-income settings may compromise their efficacy. And where they prove effective, who will fund the continued implementation of the intervention? Greater debate is needed among high-, middle-, and low-income countries to understand the ethical issues peculiar to each setting and to develop ethical guidelines for the conduct of community-based interventions.

Intervention activities

Types of interventions

The content of community interventions can include changes in public policy, the environment, community norms, or personal behaviours at both the individual and community levels. In broad terms, intervention programmes can be grouped into four types: (1) individual-level programmes, such as self-study manuals, one-to-one communication or counselling, and peer education programmes; (2) group interventions such as educational programmes in schools or with informal groups such as support organizations of drug users or sex workers; (3) mass media campaigns such as radio and television advertisements or newspaper stories; (4) public policy changes, such as mandated non-smoking areas in public places and the use of seat belts; and (5) structural interventions, such as the building water and sanitation infrastructure and public exercise equipment. Often community-wide interventions include programmes of each type. Choosing which types of interventions to use should be determined by the characteristics of the communities, the diseases of interest, cost, feasibility, and other factors.

Individually targeted, intensive interventions may be of limited use in community trials because participation in these kinds of programmes is low, and thus the population-level impact will be small. Group intervention may also have limited reach, though have additional benefits such as development of support groups. On the other hand, mass media campaigns can have a wide reach at low cost, but necessarily have a broad message which may be unable to correct misconceptions and may be lost among the plethora of media options now available (Wakefield et al. 2010). Policy changes, if enforced, can have tremendous impact, but may need to be accompanied by media messaging or information dissemination to make people aware of the change (Wongkhomthong et al. 1995).

Generally, a combined approach is more likely to be effective than one which uses only one approach because the combined approach will reach a wider audience. For example, the Indian intervention to promote exclusive breastfeeding employed a combination of interventions, namely: (1) individual counselling by traditional birth attendants, immunization clinic nurses, and healthcare workers; (2) meetings between the healthcare workers and community representatives who in turn held neighbourhood meetings to promote breastfeeding among women in the community; and (3) printed educational materials including pamphlets, posters in clinics, flip books for health workers, and counselling guides to solve common breastfeeding problems (Bhandari et al. 2003). In Guatemala, an intervention to increase awareness of danger signs during pregnancy, delivery, and the postpartum period used: (1) a clinic-based programme which trained health providers on prenatal counselling and provided educational media to patients, (2) a community-based programme consisting of radio messages about obstetric complications, and (3) education sessions conducted through women's groups (Perreira et al. 2002). The components of a health, water, and sanitation intervention in Bolivia that targeted improving health and nutritional status of vulnerable women and children used: (1) community health promoters who provided one-on-one and group-based health and nutrition education, (2) school breakfasts, (3) engagement of parents in school feeding activities, (4) establishment of school gardens, (5) culturally-sensitive maternal and child health activities to address harmful traditional health practices, and (6) used food as compensation for the time spent participating in intervention activities (Eder et al. 2012).

Appropriateness of intervention messages

Community interventions, particularly those that try to change people's behaviour, need to be carefully tailored to the target audience. Even those interventions that test treatments requiring only a minor change in behaviour encounter difficulties in ensuring compliance among patients. Thus the sensitivities of the target population should be integrated into intervention messages. For example, sex workers may be more receptive to HIV/sexually transmitted infection prevention messages when they are put in the context of fertility (Liao et al. 2003). However, in many cases knowledge and information is not enough to create change and structural or policy interventions may be needed. An example is antismoking education among health professionals, which has largely failed on its own, while strategies that have included policy interventions, such as regulations prohibiting smoking in hospital settings, have been more effective in stopping health professionals from smoking around clinical settings (Smith et al. 2005).

Difficulties in message framing are often exacerbated in low- and middle-income countries by limited education. For example, people may not understand how chronic behaviour, such as long-term smoking, can lead to adverse health consequences many years later. Thus the literacy levels of the population should also be taken into account.

Religion can pose a barrier, an obvious example being proscription by the Catholic Church of condom use to prevent HIV/STD infection. However, there are some examples where religion has successfully been incorporated into intervention activities. For example, harm reduction for drug users in Muslim communities

has been advocated on the basis that it is the lesser of two harms (Kamarulzaman and Saifuddeen 2010).

Intensity of the interventions

How much intervention is less than enough, how much is just enough, and how much is more than enough depends on such variables as the nature of the intervention, the characteristics of the target population, and the cultural characteristics of the society or community. Thus no guidelines can be formulated to cover all circumstances. Answering this question can be incorporated into the study design. For example, in the study to promote exclusive breastfeeding in Mexico City, two intervention groups with different counselling frequencies, six visits and three visits, were compared with a control group that had no intervention (Morrow et al. 1999). Infants were followed up until 3 months of age to assess the effect of the peer education programme on promoting exclusive breastfeeding and on the incidence of diarrhoea among children. Exclusive breastfeeding was achieved in 67 per cent in the six-visit group, 50 per cent in the three-visit group, and 12 per cent in the control group.

Often a community health intervention trial can be designed, funded, and implemented in a place where other health-related programmes may already be under way with public and/or private sponsorship in both experimental and control communities. Many community intervention trials may be testing only an incremental increase in the general level of health promotion in intervention communities, not the effectiveness of the intervention alone. Any community intervention programme must be sufficiently potent to be 'heard' beyond the background noise of ongoing health promotion activities. Thus an intervention programme should direct resources toward interventions that are relatively unique and not available in control communities.

Sustainability of interventions

The sustainability of an intervention is one of the most important issues in conducting community-based interventions in low- and middle-income countries. Several factors likely affect sustainability. First, the cost-effectiveness of the intervention. The cheaper the intervention is, the more sustainable the programme is likely to be. In the Mwanza STD study, during the 2 years of follow-up, 11,632 cases of STDs were treated in the intervention health units; 252 HIV infections were averted each year in the intervention group compared with control group. The average per capita cost was US\$0.39. It was estimated that the average cost per disability-adjusted life year (DALY) saved was US\$10 (range: US\$2.51–47.86). The estimated cost-effectiveness of the intervention, that is, improved treatment services for STDs, compared favourably with the cost of childhood immunization programmes, US\$12–17 per DALY (Gilson et al. 1997). If the intervention can generate profits, community may be more likely to sustain it after study completion.

Second, the simpler the intervention is, the more sustainable the programme will be. In a study on reducing childhood mortality in Nepal (Pandey et al. 1991), the intervention programme focused on active case detection. Every day each health worker visited 10–15 households with children under 5 years of age, most within a half-hour walk from the worker's home. The worker completed a round of the target households (about 160) under his/her responsibility every 2 weeks. The intervention occupied about half his/

her time and allowed him/her to continue his/her regular farming activities.

Third, the higher the proportion of people in the community covered by the intervention, the more likely the programme will be sustained. In the Rakai STD study, all consenting adults were given treatment (Wawer et al. 1998); that is, the STD rate in the community was reduced for the period of the trial and this would have at least a medium-term impact on keeping levels of infection low. However, without continued availability of free treatment to address new infections, the long-term sustainability is limited.

Fourth, the higher the intensity of the intervention, the less likely the programme will be sustained because maintaining high intensity is usually expensive, difficult, and often results in 'burn-out'. However, if the intensity is not high enough, the programme may not be able to produce changes.

A careful review of what really makes interventions sustainable appears to be unavailable, probably because few research groups return to their study site years later to examine the sustained effect of the intervention. Researchers may be unable to source the necessary funding to conduct a re-evaluation many years later and may have moved on to other fields. Many interventions are conducted with donor support and do not follow a rigorous scientific method. Donors may require some limited evaluation, but do not require very long-term evaluation. One group in Bolivia returned to villages 6 years after a comprehensive donor-funded health, nutrition, water and sanitation intervention had ended to evaluate whether the intervention practices had been sustained (Kain et al. 2004). Compared with control communities, intervention communities continued to have more functional water systems, that were better maintained, but maintenance of latrines in households was less impressive. In addition, more intervention households continued to practise positive maternal and child health behaviours. Communities which had received both development and health investments were better off than those which received only health or development assistance. This type of long-term follow-up should be done more often to assess the true, long-term impact of an intervention.

Measurement

While the unit of intervention in community-based trials is the community, the unit of measurement is often the individual. Since the overall aim of a community-based intervention programme is generally to reduce mortality and/or morbidity, these two measures are commonly used indicators of the impact of the intervention. In the childhood mortality studies in Nepal (Pandey et al. 1991; Manandhar et al. 2004) and India (Bang et al. 1990) neonatal, infant, and child mortality was used as the outcome variable. Maternal mortality was an outcome in an antenatal care intervention in Bangladesh (Bang et al. 1990) and Nepal (Manandhar et al. 2004). In three STD studies conducted in Africa, the incidence rates of STDs and HIV infection were used to evaluate intervention effects (Grosskurth et al. 1995; Wawer et al. 1998; Kamali et al. 2003). Morbidity may also be measured not only as disease incidence measured through biological methods, but also by using psychosocial measures. A number of these now exist to measure quality of life, addiction, depression, and other psychological symptoms, many of which have been translated and tested in the context of low- and middle-income countries. In India, the

effectiveness of a day-care programme for the elderly was measured using standardized scales for assessing psychiatric morbidity and quality of life (Jacob et al. 2007).

Direct measures of outcome variables, such as disease incidence or mortality, provide valid data to assess the effectiveness of an intervention programme. However, determining them is often expensive. The high cost of individual-level measurements may limit the number of surveys that can be done and thus the statistical power of the evaluation. The high cost of measuring incidence often precludes long-term monitoring for latent effects, which can be important since the time lag between programme implementation and individual-level effects is often uncertain and may be long. Costs can be reduced to a certain extent by taking advantage of local health services records and using passive case detection, rather than surveying participants at specific times. In Ghana, an intervention to prevent malaria in children was measured by the incidence of malaria and anaemia as detected when children were hospitalized at any one of 11 health clinics in the study site (Chandramohan et al. 2005). In many low- and middle-income countries, however, health services may not be established well enough to make this feasible. Serial cross-sectional surveys may also reduce costs as they are usually less expensive than incidence studies.

Because of these problems, other measures are often used as surrogate markers for morbidity. Examples of surrogate or intermediate outcomes that are measured in a variety of behavioural intervention studies include knowledge, attitudes, beliefs, intentions, behavioural skills, and behaviours. In such studies, the assumption is that increasing knowledge and changing attitudes will lead to reduced risk behaviours and by reducing risk behaviours the likelihood of developing the disease is also reduced. In community-based HIV/AIDS education interventions, knowledge, sexual behaviours, and condom use behaviours may be used as outcome variables to assess the impact of the interventions. Self-reported data are cheaper because they avoid costly clinical tests. Moreover, changes in behaviour may be expected to be seen to a larger extent than changes in the frequency of disease, making sample size calculations smaller and reducing overall study expenditure.

However, data collected through self-report are less robust than objective measures such as biological testing because they may be affected by recall bias and social-desirability bias. Ideally, where funding is sufficient, self-reported behaviours are verified by more objective data, such as biological data, to verify that the changes in behaviour lead to the desired outcome, at least in the short term. Studies of condom use to prevent HIV infection will often ask participants about their risk behaviours but may verify this through biological assessments, such as testing for STDs (which generally have a higher incidence and infectivity than HIV, and hence are more likely to yield an observable change in prevalence), or observing whether participants can demonstrate correct condom use.

Other general measures can include distribution of intervention materials or demand for services. In the nationwide schistosomiasis campaign launched in Burkina Faso, the number of immunizations was one outcome used to measure coverage (Gabrielli et al. 2006). Environmental factors can also act as objective measures of the success of an intervention. In a study to increase knowledge and modify behaviours related to dengue vectors in Vietnam, the

main outcome was the prevalence of the *Aedes aegypti* mosquito larvae in water storage containers (Vu et al. 2005).

Interpretation

Interpretation of results is sometimes difficult. Cautious interpretation must be made especially when no control group is used. The Matlab study of maternal mortality in Bangladesh concluded that maternal mortality was significantly lower in areas with maternal and child healthcare programmes and family planning programmes (MCH-FP) than in the control area (Fauveau et al. 1991). However, continued observation indicated that there was no sustained difference between the MCH-FP and comparison areas (Ronsmans et al. 1997). The authors thus concluded that the introduction of the maternity-care programme coincided with declining trends in direct obstetric mortality in the areas covered by the programme, although it is also possible that the effectiveness of the intervention declined.

Even with a control group, sometimes the relative benefits of an intervention are not observable. This may be because the investigators have failed to accommodate secular trends in the community under study. Conducting a pre-baseline survey before randomization can provide data to help interpret the influence of secular trends. Qualitative data can also help to interpret secular trends. In the South Africa study, qualitative data and analytic methods that could control for secular trends were used to detect reductions in intimate-partner violence (Pronyk et al. 2006).

Appropriate statistical analysis

A key issue in interpreting results from a community-based trial is using the correct data analysis, particularly when cluster-randomization has been used. Because the analysis is complicated—requiring that both individual-level and group-level characteristics be accommodated—few researchers use the correct statistical analyses, even in high-income countries. A review of 56 papers in seven peer-reviewed journals identified few that had appropriate study designs or used the appropriate methods of analysis (Ukoumunne et al. 1999). Often, researchers fail to take into account the group or design effect and data are analysed at the individual level. By ignoring the group effect, the relative benefits of the intervention are exaggerated and the intervention may seem more effective than it really is (Donner and Klar 2000). Accounting for group and individual-level covariates can be achieved using a multilevel or hierarchical model which includes a parameter for the correlation of observations within a cluster. A number of texts now exist describing how to perform these types of analysis using commonly-used statistical programs, making these methods more accessible to researchers. (See also Chapter 5.8.)

Translating scientific studies to programme settings

Often, the scientific environment in which a study is conducted is quite different from programme settings. Investigators will often choose a study environment that will allow methodological robustness. For example, communities with low emigration are often used in scientific studies to maximize the likelihood of good follow-up of participants for the duration of the study. Scientific

studies are also generally able to expend more resources (financial, human, and time) than would be feasible if the project were later institutionalized in the routine healthcare system in low- and middle-income countries. The capacity of health workers is a key issue in scaling up evidence-based interventions. In many low- and middle-income countries, health workers, particularly those in rural areas, have only had some high-school education, with additional training in first aid and preventive medicine. Intervention activities need to be within the capabilities of the health human resources that are reasonably available or that require a level of training that is realistic given local health budgets.

In low- and middle-income countries, trials are often done to determine their effectiveness, rather than their efficacy. The differences between these two objectives are important when considering whether or not to scale up an intervention. Efficacy measures the benefits of an intervention among those who take advantage of it or the benefits of an intervention given under fairly ideal conditions; effectiveness measures the benefits of an intervention among those offered or under programmatic or 'real-life' conditions. When scaling up a community intervention programme, the overall effectiveness of a programme is more important than knowing how good it could be if people were to use it, especially when trying to determine how best to use limited resources. However, a programme is unlikely to prove effective if it has not been demonstrated to be efficacious. This extends to structural barriers that prevent people from using an intervention. In the study from Honduras that compared giving monetary incentives to women to use primary healthcare services with direct transfer of resources to local health teams, it was found that the household-level intervention had a large impact, but the transfer of resources could not be implemented properly because of legal complications (Morris et al. 2004). While the researchers acknowledged this limited interest in their findings, they stressed that their objective was to test effectiveness, rather than efficacy; the inability of the government to successfully transfer resources was therefore an important observation because of its implications for scale-up. Sometimes in community trials, particularly those conducted in low- and middle-income countries, *feasibility* is the most important study outcome.

Feasibility is greatly aided by community consultation. As mentioned earlier, consultation with key community members in the design phase of a project can aid translation of research into policy by ensuring that the study asks questions which the community regard as important. Continued communication with these parties is essential for creating the sense of ownership required for politicians and government officials to support scale-up of an intervention. Strategies that facilitate the development of relationships among members in different, responsible sectors can facilitate this process of persuasion. They are especially important when recommending the scale-up of interventions that benefit marginalized or stigmatized members of the population.

Conclusion

Community intervention trials are now used in low- and middle-income countries more than ever before and cover an increasing range of public health issues, including infectious diseases, neonatal mortality, malnutrition, and unhealthy behaviours, as well as chronic diseases. Their use is likely to continue to

increase in coming years as concern grows over the evaluation of the delivery of health services, public education, and social policy. One advantage of conducting community intervention trials in low- and middle-income countries is that they often address urgent preventable health problems in these countries. However, it is often more challenging to implement community intervention trials in these countries because of the lack of background information, lack of infrastructure, and lack of trained and experienced resource personnel. Several criteria need to be considered before beginning community intervention trials in low- and middle-income countries:

- ◆ Study sites should have a reasonably high incidence of the health events of interest.
- ◆ A qualitative study of the social and cultural characteristics of the community may need to be conducted.
- ◆ Community consultation should be carried out before finalizing the intervention plan.
- ◆ Local resources should be used for the intervention to ensure sustainability.
- ◆ The type, intensity, and quality of the intervention must be considered acceptable and culturally sensitive to the communities.
- ◆ Simplicity, affordability, and sustainability of intervention strategies should always be emphasized.

Community interventions have been demonstrated to be effective in low- and middle-income countries but more trials are needed for the many public health problems still affecting these countries.

Acknowledgements

The authors are especially grateful to Professors Roger Detels and Mary Ann Lansang for their comments, suggestions, and helpful editing. The authors would also like to thank Ms Line Handlos-Neerup for her assistance with the literature review.

Clinical epidemiology

Vivian A. Welch, Kevin Pottie, Tomás Pantoja, Andrea C. Tricco, and Peter Tugwell

Introduction to clinical epidemiology

In many university settings there is often a differentiation between social or public health epidemiology and clinical epidemiology. Clinical epidemiology emerged as the application of epidemiology principles for the study of individuals in clinical settings.

Clinical epidemiology was defined by Alvan Feinstein in 1968 as: ‘the clinicostatistical study of diseased populations. The intellectual activities of this territory include the following: the occurrence rates and geographic distribution of disease; the patterns of natural and post-therapeutic events that constitute varying clinical courses in the diverse spectrum of disease; and the clinical appraisal of therapy’ (Feinstein 1968).

The *Journal of Clinical Epidemiology*, a leading journal in its field, believes its role is to promote the quality of clinical epidemiological and patient-oriented health services research through advancement and application of innovative methods of conducting and presenting primary research; synthesizing research results; disseminating results; and translating results into optimal clinical practice. While clinical epidemiology originally intended to focus on studies that would inform clinical practice, recently clinical epidemiology methods have informed pragmatic trials that are an important part of public health intervention research. Pragmatic trials are designed to evaluate the effectiveness of interventions in real-life conditions, whereas efficacy trials aim to test whether an intervention works under optimal conditions. Pragmatic trials are attractive for public health in that they produce results that can be generalized and applied in various communities. A shift in recent years to pragmatic trials reflects a desire for more generalizable research. However, there are limitations to pragmatic trials such as high cost for large trials.

While epidemiology is focused on the study of distribution of disease and determinants (Last 1996), clinical epidemiology involves extrapolating results from best available evidence (including experimental studies such as randomized trials as well as non-randomized studies) to individual patients in a clinical setting. Clinical epidemiology evolved to also extrapolate results to populations. For example, the Framingham study on cardiovascular risk factors was designed to inform decisions about both individuals and populations. Clinical epidemiology was disseminated widely throughout low- and middle-income countries by the International Clinical Epidemiology Network (INCLIN), an initiative funded by the Rockefeller Foundation in 1980 (Box 5.11.1).

In the 1990s, the term ‘evidence-based medicine’ was coined by Gordon Guyatt, and subsequently defined by Dave Sackett in 1996 as: ‘Evidence based medicine is the conscientious, judicious and explicit use of current best evidence in making decisions about the care of individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research’ (Sackett et al. 1996). In 1993, the Cochrane Collaboration was formally launched with the mission to assemble the best available evidence about effects of healthcare interventions. Although this work was initially primarily focused on synthesizing evidence from randomized trials, the Cochrane Collaboration has formally recognized the importance of non-randomized studies for particular questions, such as studying upstream public health interventions.

Indeed, there is a growing emphasis within the Collaboration on evidence-informed decision-making for public health. The Cochrane Public Health Group was registered in 2008, with a mandate to assess effects of social and structural interventions on population health such as the effects of obesity prevention messages, social housing improvements, social policies, and transport interventions. The World Health Organization (WHO) Commission on Social Determinants of Health included a Measurement and Evidence Network which promoted the role of systematic reviews in providing the evidence base for action on health equity and social determinants of health. In the United States, the Community Guide, associated with the Centers for Disease Control and Prevention, has developed explicit methods to develop evidence-based preventive guidelines on topics such as obesity prevention, traffic injuries, and improving population mental health. The National Institute for Health Research in the United Kingdom asks all grant submissions to refer to existing systematic reviews on the topic to establish the need for further research in light of these reviews, including the Public Health Research Programme.

Evidence-informed public health has been defined as: ‘The process of distilling and disseminating the best available evidence from research, practice and experience and using that evidence to inform and improve public health policy and practice’ (Ciliska et al. 2010). There is an increasing application of clinical epidemiology methods to appraise evidence about public health interventions such as hand-washing, obesity prevention, and vaccination. For example, one of us (AT) is involved in a review of the efficacy of influenza vaccines in healthy adults when the antigens in the vaccine do not match those of circulating strains (Tricco et al. 2012). Mismatched strains

Box 5.11.1 The International Clinical Epidemiology Network (INCLEN)

INCLEN (<http://www.inclenrtrust.org>) began as a strategy funded by the Rockefeller Foundation in 1980 to improve health-care by providing health professionals, mostly physicians, with the necessary tools to plan, measure, and evaluate clinical care. Healthcare professionals, empowered in such a fashion, would provide an essential link to help develop functional health and health research systems in low- and middle-income countries. Currently with over 1500 members, the network has trained physicians and other health specialists at a Master's degree level in clinical epidemiology, social sciences, biostatistics, or clinical economics. This strategy has built a global resource network to support fundamental changes in the way physicians, medical educators, and policymakers think about health and disease. INCLEN has semi-autonomous regional networks in Africa, India, China, South East Asia, Latin America, Europe-Mediterranean, and Canada-United States.

INCLEN's long-range goals are to strengthen national health systems and to improve healthcare practice globally by providing health professionals with the tools to analyse the efficacy, effectiveness, efficiency, and equity of health interventions and preventive measures.

A recent series of articles in the *Journal of Clinical Epidemiology* highlights the continued contributions of INCLEN to public health in the areas of measurement tools for developmental delay in children, pneumococcal infections, and tuberculosis (Thomas 2013).

occur frequently—there was a mismatched influenza B strain in the influenza vaccine for six of the 11 previous flu seasons in the United States (Centers for Disease Control and Prevention 2012). This review is of relevance to public health, because mismatched strains can lead to reduced vaccine effectiveness, which may result in reduced uptake of influenza vaccination and subsequently, more severe influenza epidemics.

The application of clinical epidemiology to both public health and clinical questions requires structured methods to consider effects on health equity. For example, a theory-based approach is suggested to consider plausible mechanisms of action of public health interventions on health inequity (Anderson et al. 2011). The use of visual logic models or analytic frameworks may help to describe the causal pathways and assumed mechanisms of action for complex public health interventions.

For public health, as in clinical medicine and healthcare, evidence must be assessed according to whether it is 'fit for purpose', rather than using an evidence hierarchy (Tugwell 2010). However, the different non-randomized studies need to be assessed for risk of bias, particularly due to confounding (Higgins and Green 2011). Higgins and Green define non-randomized study designs as 'any quantitative study estimating the effects of an intervention (harm or benefit) that does not use randomization to allocate units to comparison groups' (Higgins and Green 2011). Recent reporting guidelines for equity-focused systematic reviews, many of which are focused on public health questions such as obesity prevention, recommends reporting the justification for including different types of study designs (Welch et al. 2012).

In some areas of public health, there is conflict between non-randomized and randomized studies. For example, meta-analysis of prospective cohort studies found that people with higher dietary salt intake have a greater risk of stroke compared to people with lower salt intake. In contrast, a recent Cochrane review of seven randomized evaluations of advice to reduce salt intake found insufficient evidence of effects on all-cause mortality, cardiovascular mortality, or blood pressure due to sparse data (Taylor et al. 2011). Similarly, the Institute of Medicine in the United States convened an expert panel to assess the evidence from a comprehensive review of both observational and randomized studies and concluded that reduced dietary salt intake may increase adverse effects in some subgroups and there is little evidence to support salt reduction for preventing mortality or cardiovascular disease (Strom et al. 2013). The two recent reviews both concluded further research with sufficient power and appropriate design is needed to assess the effects of salt reduction on mortality. Thus, in public health, there is a need to consider different types of evidence and to critically appraise the risk of bias for the outcomes of interest.

For some public health questions, non-randomized studies which are designed to control for confounding may be better suited to providing evidence about effectiveness. For example, in a review of interventions to improve water quality, 39 out of 44 studies of effectiveness of environment and sanitation measures were non-randomized studies (Snilstveit and Waddington 2009). However, it is important to assess the risk of bias in these studies. Another example of including non-randomized studies is a recent Cochrane systematic review of obesity prevention for children which found that educational and behavioural interventions are effective at reducing body mass index in children from lower socioeconomic status settings, and there was no evidence of increases in health inequalities (Waters et al. 2011). A third example is a review of policies to reduce child consumption of sugar-sweetened beverages, such as reduced accessibility of vending machines in schools and price regulation through taxes (Levy et al. 2011). This review also included non-randomized studies, and found that price increases through taxation reduce consumption and may be more effective for children at greatest risk of overweight and from lower income families.

Systematic reviews on public health interventions and policies are increasingly available. For example, the Health Evidence database (<http://www.healthevidence.org/>) now contains over 3000 quality-appraised systematic reviews related to public health identified from searches of the Cochrane Database of Systematic Reviews, MEDLINE, Sociological abstracts, PsychINFO, and handsearching of 46 public health and health promotion journals.

In the next section, we will use the equity-effectiveness framework to illustrate six steps of evidence-informed public health that highlight the interface between public health and clinical epidemiology of assessing the burden of illness (need), the effects on population health and health inequity, economic evaluation, implementation, monitoring, and reassessment.

Interfaces between clinical epidemiology and public health

Other functions of clinical epidemiology that contribute or interface with public health include screening programmes, health technology assessment, and standards setting (through practice guidelines and quality improvement).

Screening is an important part of primary care, typically done by family physicians and nurse practitioners. Good examples of an evidence-based approach to this include the Canadian Task Force on the Periodic Health Exam, Canadian Task Force on Preventive Healthcare (<http://canadiantaskforce.ca/>), the US Preventive Services Task Force (<http://www.ahrq.gov/clinic/uspstfix.htm>), and guidelines for disease promotion in immigrants and refugees in Canada (Pottie et al. 2011). Many of these screening clinical actions need to be integrated with public health services.

Health Technology Assessment, defined by Battista as the bridge between science and policy, also bridges clinical epidemiology and public health. Indeed one of us (PT) has used the same stepwise iterative loop approach to systematizing the methods (Tugwell et al. 1995). Health equity impact assessment is gaining interest as a method to explicitly consider effects of policies and programmes on health equity (Povall et al. 2013).

Standards setting through practice guidelines and quality assurance in clinical epidemiology also has many parallels with public health, especially public health units. Clinical guidelines are only as good as the evidence and judgements they are based on. For example, the international GRADE initiative has been developed for users of clinical practice guidelines and other recommendations to provide them with the information needed to know how much confidence they can place in the recommendations. Systematic and explicit methods of making judgements can reduce errors and improve communication. The GRADE system grades the quality of evidence and the strength of recommendations that can be applied across a wide range of interventions and contexts. Judgements about the strength of a recommendation require consideration of the balance between benefits and harms, the quality of the evidence, translation of the evidence into specific circumstances, and the certainty of the baseline risk. It is also important to consider costs (resource utilization) before making a recommendation. Inconsistencies among systems for grading the quality of evidence and the strength of recommendations reduce their potential to facilitate critical appraisal and improve communication of these judgements. This system for guiding these complex judgements balances the need for simplicity with the need for full and transparent consideration of all important issues. These are being used not only for clinical guidelines but also to assess quality of evidence for each outcome in a systematic review and at the policy level. For example, the WHO used GRADE to assess the evidence for antivirals for avian influenza (Schunemann et al. 2007) and cryotherapy for cervical cancer prevention (Santesso et al. 2012).

An example of a public health guideline is the *Treating Tobacco Use and Dependence: 2008 Update* clinical practice guideline (Fiore et al. 2008). This initiative was sponsored by the Public Health Service and conducted by collaborative efforts among eight US federal government and not-for-profit organizations, including the Agency for Healthcare Research and Quality (AHRQ). The guideline was based upon a comprehensive systematic review, for which over 8700 titles and abstracts were screened. Three strength of evidence ratings were applied to each of the recommendations, with well-conducted randomized clinical trials being the highest level of evidence and consensus being the lowest level of evidence. Meta-analyses were conducted on 11 pre-defined topics and ten key guideline recommendations were formulated. These included encouraging all smokers to try effective counselling interventions, such as telephone and

group counselling, as well as medications, such as nicotine gum and varenicline. In order to increase the uptake of the clinical practice guideline, executive summaries were tailored for health policymakers, clinicians, and patients. Furthermore, smokers are provided with access to a website to help them quit smoking, as well as a phone number for a quitline service. Such knowledge translation strategies increase the likelihood that key recommendations will reach the target audience.

The equity–effectiveness framework to assess the interface between clinical epidemiology and public health

Clinical epidemiology and its derivative—the evidence-based medicine movement—have many parallels with public health. Indeed many clinicians with clinical epidemiology training develop research projects and subsequently research programmes that move beyond clinical decision-making to include a population focus. This stimulated one of us (PT) and his colleagues to address this process systematically through an iterative measurement loop framework (Tugwell et al. 1985). The focus was on evidence-based, action-oriented epidemiology based upon the health needs of the relevant individuals and their community.

This has been updated with an ‘equity lens’ to ensure that disadvantaged populations are explicitly considered (Tugwell et al. 2006a) (see Fig. 5.11.1). What was the stimulus to incorporate explicit attention by clinical epidemiologists to the disadvantaged? This was due to the realization that average improvement can hide important inequitably worse health effects amongst the disadvantaged. For example, impressive gains in health during the twentieth century, showing dramatic increases in average life expectancy in rich and poor countries (WHO 1999), would meet the criteria we initially recommended in the 1985 paper, but there is a critical component missing. These averages obscure the fact that health in both high- and low-income countries is unevenly distributed according to socioeconomic position; health and longevity are highest for the richest, and decrease steadily with decreasing socioeconomic status (Wilkins and Adams 1983; Wilkinson 1996). Where these inequalities in health are avoidable by action or policies and they are considered unfair, they meet the criteria for being considered health inequities (Whitehead 1990). The judgement of fairness is normative and depends on context. For example, in countries where health is viewed as a commodity not a right, the judgement about the fairness of health inequalities or disparities may differ.

These social gradients in health, or socioeconomic inequalities in health, are pervasive in all countries of the world (Diderichsen et al. 2001) and hold true for most diseases, injuries, and health behaviours. For example, globally, childhood obesity has increased dramatically since 1990 from 4 per cent to 7 per cent. The association of childhood obesity with socioeconomic status varies depending on gender, age, and country. Those with low socioeconomic status in higher-income countries and those with higher socioeconomic status in lower-income countries have higher exposure to energy-dense diets and higher risk of obesity (Wang and Lim 2012). In the United States, the prevalence of childhood obesity in boys is 21 per cent in those living below 130 per cent of the poverty level compared to 12 per cent in boys from families at 350 per cent above the poverty level (Ogden et al. 2010). Modern health policy must increasingly be oriented not only to

Fig. 5.11.1 Equity–effectiveness framework. SES: socioeconomic status.

the production of health, but also to the distribution of health and health equity (Gwatkin 2003). The WHO Commission on Social Determinants of Health and the recent Rio Commission meeting drew attention to the need for an improved evidence base to tackle avoidable and unfair inequalities in health.

The ‘equity–effectiveness iterative framework’, was developed to address this need for evidence about both improving population health and reducing health inequities. This framework has been expanded to provide a logical way to apply an ‘equity lens’ as one moves from assessing needs and burden of disease through to assessing effectiveness, and cost-effectiveness, of interventions, leading to the development and evaluation of evidence-based health policy, as well as scaling up from proof of concept to a population level. This framework integrates the concepts of individual risk and socioeconomic status with intervention effectiveness from a population health perspective.

Step 1: burden of illness

This step measures the burden of illness and its gradient by socioeconomic status. This includes downstream (individual) and upstream (societal) determinants of health (biological, cultural, political, psychosocial, and environmental). Health information systems and routinely collected data are important for assessing not only the overall burden of illness but also differences across socioeconomic status and other factors associated with inequities in health such as sex/gender and urban versus rural settings.

Step 2: differential equity–effectiveness

Controlled studies provide estimates of efficacy and effectiveness; efficacy measures how well an intervention can work in ideal circumstances (Sackett et al. 1985). Effectiveness measures how well an intervention works in real settings and systems at

the community level. Community effectiveness is often substantially lower than efficacy because of a staircase effect with four ‘steps’: (1) the result of lower awareness, access, or coverage; (2) screening, diagnosis, or targeting; (3) compliance of providers; and (4) adherence of consumers. Poor people may have circumstances that reduce efficacy at all four steps and therefore a greater staircase effect may be observed compared to the least poor people. There is a need to assess equity issues across each step to identify barriers to implementation related to gradients in wealth.

Step 3: economic evaluation

This step assesses the efficiency (health benefits such as number of disability-adjusted life years avoided for a specific cost that includes direct, indirect, and where possible intangible costs) of the intervention. Assessing the efficiency requires adequate evidence of efficacy and valid estimates of cost. Assessing the equity issues related to cost-effectiveness implies a trade-off between cost efficiency and population health equity. Priority funding of interventions with the best cost-effectiveness ratios might increase differences between the richest (or least poor) and poorest because the cost of reaching poor people may be higher and health benefits may be lower. Four approaches to this have been proposed (Drummond et al. 2006). One promising method to assess equity issues related to cost-effectiveness is the development of an equity and quality-adjusted life year (EQ-QALY), as a complement to established measures of the difference between rich and poor, such as the concentration index (Wagstaff 2002).

Step 4: knowledge translation and implementation

Translation of knowledge is defined as the process that transfers research results from producers of knowledge to its users,

for the benefit of the population. Moving beyond the traditional domain of academic publication, it comprises three interlinked components of uptake and translation: exchange, synthesis, and ethically sound application of knowledge (Birdsell et al. 2002). This step entails uptake and translation of knowledge into action (Grimshaw et al. 2001; Birdsell et al. 2002; Davis et al. 2003).

There is therefore a need to develop new, effective means of packaging and communicating evidence on effectiveness across wealth gradients to the different policy, community, and practitioner groups or individuals responsible for each of the components of community effectiveness—access, diagnostic accuracy, compliance of providers, and adherence of consumers (Giuffrida et al. 2000; Zwarenstein and Bryant 2000; Briggs et al. 2001; Mowatt et al. 2001). Evidence that interventions using knowledge translation are efficacious is currently lacking in most sectors. One exception is the work of INCLIN (see Box 5.11.1), which is developing methods explicitly to consider equity issues in developing and applying clinical guidelines (INCLIN 2004). By targeting the wealth gradient in knowledge translation strategies, we support the operational research agenda for optimizing the benefits to the poor of key interventions.

Steps 5 and 6: monitoring and reassessment

Monitoring identifies the importance of process assessments and intermediate outcomes to assess success in affecting mortality and morbidity by socioeconomic group and deciding whether further remediable need exists; if so, an additional iteration of the equity–effectiveness loop is needed. The Whitehall cohort study, for example, showed that, even with equitable access to cardiac care, the social deprivation gradient still produces disparities in outcomes (Britton et al. 2004), indicating a need to tackle other causes, or ‘steps’, of disparities.

Applying the equity–effectiveness framework step by step

We elaborate on the application of the equity–effectiveness loop using the example of school lunch and breakfast programmes for disadvantaged children. School feeding programmes are described by the World Food Programme as tools to combat hunger, nutritional deficits, educational attendance, and gender inequalities (www.wfp.org/school-meals/in-depth). They are considered a transfer to impoverished families (Alderman and Bundy 2012). However, there is some controversy about school feeding programmes because of the epidemiological transition leading to increased obesity in disadvantaged children in both high-income countries and lower-income countries. We will examine the effects of school feeding in detail using the equity–effectiveness framework.

Step 1: burden of illness

Undernutrition is the largest cause of global burden of disease and predominantly affects children. Childhood undernutrition is responsible for a third of mortality and disease burden in children under 5 years old. It also has long-term effects on physical and cognitive development. Childhood malnutrition is inversely associated with income in all developing countries, and meets the criteria of being inequitable since child malnutrition is both avoidable and unfair (Van de Poel et al. 2008). Burden of illness

can be measured by household surveys or by routinely collected health data. There is increasing attention to also collecting indicators of socioeconomic status alongside health data to allow an assessment of differences in health status between different populations and settings.

Step 2: efficacy, community effectiveness, and differential equity–effectiveness

When asking questions about effectiveness and efficacy, clinical epidemiology provides critical appraisal tools to identify studies at the lowest risk of bias for the question of interest. For example, non-randomized studies of school feeding have shown larger effects on weight gain and cognition, partly because they are unable to control for bias in the measurement of outcomes.

For a public health decision to be evidence-informed, policy-makers should follow clear steps in: (1) formulating a question, (2) seeking the best available evidence, (3) determining the quality of that evidence, and (4) determining the applicability of the evidence to their settings.

1. *Formulating a question:* any well-designed question should be composed of the following four criteria: PICO—Population, Intervention, Control, and Outcome. Some questions, particularly those related to public health, may need to specify context, study design or time of follow-up.
 - a. For school feeding, in disadvantaged children (population), does school feeding (intervention) improve health, cognition, and attendance (outcome) in comparison to control (control)? This structured question addresses all of the important components of an answerable question.
2. *Seeking the best available evidence:* for the purpose of this chapter, we searched the Health Evidence database which is a collection of systematic reviews that address public health questions (Tirilis et al. 2011). We used the terms: ‘school AND (feeding OR lunch OR breakfast OR meal OR snack)’. We identified 25 reviews with these terms.
3. *Determining the quality of the evidence:* we then assessed the relevance of each systematic review in answering our question. Only one review was relevant to our question (Kristjansson et al. 2007). This review is rated as strong quality using the Health Evidence quality appraisal tool (score of 10 on a scale where the maximum possible is 10). If no systematic review exists, then you may need to search for primary studies and apply the same steps, or consider conducting a systematic review. Guidance for conducting a systematic review, including how to develop a search strategy, can be found from the Cochrane Collaboration handbook (Higgins and Green 2011).
4. *Applying the findings to the target populations:* this Cochrane systematic review found that children who received school feeding had a 13.5 per cent increase in growth rate relative to a control group, measured as an absolute difference of 0.39 kg (95 per cent confidence interval of 0.11–0.67 kg). Implementation of school feeding requires consideration of a number of factors (Greenhalgh et al. 2007) such as local context and preferences, possible leakage to family members, and substitution or displacement of a child’s regular meals at home.

Differential effectiveness

Controlled studies provide estimates of efficacy, that is, how well an intervention can work in ideal circumstances. The equity–effectiveness framework takes efficacy as the anchor point representing the maximum benefit that can be achieved. Community effectiveness is the measure of how well an intervention does work when delivered in real-life settings and systems at the community level. This ‘community effectiveness’ is often substantially lower than the expected efficacy because of four systemic factors: awareness/access/coverage, screening/diagnosis/targeting, provider compliance, and consumer adherence.

School feeding is a good example of differential effectiveness across socioeconomic status

The relative improvement in growth of 13 per cent is expected to be the same for both poorest and least poor children. However, there are differences in access (estimated by school participation rate) and consumer adherence (increased rates of leakage and substitution in the poorest families). These two factors lead to a reduction in community effectiveness from 10 per cent in the least poor (most advantaged) to 4 per cent in the poorest (Table 5.11.1).

Step 3: economic evaluation

This step assesses the efficiency (health benefits (number of lives saved, number of quality/disability-adjusted life years avoided)) obtained for a specific cost (direct, indirect, and where possible the intangible costs expressed in monetary units such as dollars, euros, or pounds) of the intervention. That is, whether the intervention is being delivered to those who would benefit from it with an optimal use of resources. Assessment of efficiency should not be done in the absence of adequate evidence of efficacy and valid estimates of cost. Application of an equity lens to this step implies a trade-off between cost-efficiency and population health equity. Priority funding of interventions with the best cost-effectiveness ratios might increase rich–poor differences because the cost of reaching the poor may be higher (e.g. distance to care) and health benefits may be lower. The concept of using equity-adjusted traditional utility metrics such as an EQ-QALY needs to be developed, as described earlier.

For the case of school feeding, cost studies were conducted to assess the cost per child and cost per outcome, based on a Cochrane systematic review (Galloway et al. 2009). The results show the cost per extra day of attendance of \$4.7 to \$15.8 and the cost per extra kilogram of weight ranged from \$112 to \$252. Comparability of these results to other health and education

interventions will be enhanced when the cost analyses for different interventions are performed using the same methods and the same outcomes.

Step 4: implementation

The implementation of school feeding is critical to the success of the programme. For example, school feeding programmes designed with community involvement and palatability testing were more successful. Furthermore, there is a need to minimize substitution by using snacks which are less likely to lead to meal substitution.

The science of implementation overlaps substantially with the recently burgeoning ‘knowledge translation’ initiatives—see the following ‘Knowledge translation and innovation’ section.

Steps 5 and 6: monitoring and reassessment

Monitoring identifies the importance of process assessments and intermediate outcomes (putting the human and physical resources in place, monitoring the identification, and treatment of those at risk/in need). The main purpose of these steps in the equity–effectiveness framework is to assess success in affecting mortality and morbidity by socioeconomic group and deciding whether further remediable need exists; if so, there needs to be an additional iteration of the framework.

Monitoring of any scaled-up programme for school feeding is essential; just applying the evidence alone will be insufficient. For example, monitoring is needed to assess acceptability of food, unintended consequences, and substitution of meals at home by meals at school.

An example of an equity-focused approach to monitor health programmes is the Equity Gauge of the Global Equity Gauge Alliance, funded by Rockefeller Foundation. This group developed ‘equity gauges’ as a means of tracking gaps in health at the national or sub-national levels (McCoy et al. 2003). This approach to equity includes three pillars: (1) measuring key indicators, (2) public participation, and (3) advocacy. Inclusion of all three pillars aims at bringing about evidence-based action. Equity Gauges have been or are being developed in Bangladesh, Chile, China, Ecuador, Kenya, South Africa, Thailand, Uganda, Zambia, and Zimbabwe (McCoy et al. 2003).

The WHO has developed a Health Metrics Network to enable performance-based monitoring of interventions and health systems. The Network aims to build transparency and accountability, and ensure that policy decisions are based upon evidence. Equity is central to the proposed data indicators (AbouZahr and

Table 5.11.1 Equity–effectiveness framework applied to school feeding

	Efficacy	Efficacy modifiers				Community effectiveness	Least poor: poor equity–effectiveness ratio
		Access	Diagnostic accuracy	Provider compliance	Consumer adherence		
• Least poor	13%	97%	95%	90%	91%	10%	2.5
• Poorest	13%	73%	95%	80%	49%	4%

Boerma 2005). The Institute for Health Metrics and Evaluation led by Dr Chris Murray has recently published updated global burdens of disease and their association with 67 risk factors. These country-wide data can be used to monitor changes over time in burden of disease in populations. For example, the recent analyses show an increase in non-communicable diseases in adults, relative to a decreasing burden of communicable diseases in children (Lim et al. 2012).

Our stepwise illustration of the equity–effectiveness framework concludes here, showing the interface between clinical epidemiology and public health.

Knowledge translation and innovation

This is an aspect of clinical epidemiology that has developed in the last 10 years, stimulated in part by being singled out for funding by agencies such as the Canadian Institutes of Health Research (CIHR). This is highly relevant to public health and warrants discussion here.

The CIHR defines knowledge translation as a ‘dynamic and iterative process that includes synthesis, dissemination, exchange and ethically-sound application of knowledge to improve the health of Canadians, provide more effective health services and products and strengthen the health care system’ (Straus et al. 2009). This involves uptake and translation of knowledge into ethically sound action. To do this, tailored interventions are needed to reach a range of target groups, including researchers, local and national policymakers, professionals, affected communities, industry, media, and the general public. However, one of the primary challenges facing these initiatives is to determine the most effective strategies to promote the use and application of research.

In public health, there is an important role of legislation and regulation in knowledge translation. For example, smoking bans have been showcased as an intervention that has been effective in many different settings for reducing smoking prevalence. However, there is a need to balance the evidence of effectiveness with any infringement on moral values such as individual autonomy or injustice in the distribution of effects of the interventions. For example, workplace smoking bans have been shown to increase inequalities in smoking across socioeconomic status (Lorenc et al. 2012). The widely publicized initiative by the city of New York to ban the sale of soft drinks in sizes larger than 16 ounces was overruled on the basis that the mayor exceeded his legislative authority (Saul 2013). There is an increasing need for policy innovations in law and regulation to tackle global problems such as the increasing burden of non-communicable disease, and these need to include multiple stakeholders such as government, private sector, and civil society (Gostin et al. 2013).

There are numerous models and frameworks for developing knowledge translation strategies, depending on the target audience as well as other characteristics. We next describe two case studies of knowledge translation: (1) Canadian Collaboration for Immigrant and Refugee Health Knowledge Exchange Network (CCIRH KEN), and (2) Evidence into Policy Network (EVIPNet).

Case Study: Canadian Collaboration for Immigrant and Refugee Health Knowledge Exchange Network

The CCIRH KEN (<http://www.ccirhken.ca>) began in 2007, funded by the Public Health Agency of Canada. Its strategy was to improve the healthcare of a vulnerable population by providing primary healthcare practitioners with the necessary evidence-based guidelines to effectively manage newly arriving immigrant and refugee patients. Newly arriving immigrants and refugees depend on community-based primary healthcare practitioners for decision support and healthcare system navigation. In addition, immigrant communities often connect to national and international diaspora networks for decision supports and resources. Thus, a long-range objective of the evidence-based initiative was to create guidelines and decision support tools to assist vulnerable migrants that could be used in Canada and in other migrant-receiving countries.

Currently with over 400 members, the CCIRH KEN has provided clinical guidelines, methods, narrative podcasts, and e-learning programmes for physicians and other health practitioners as well as medical and graduate students. The network has also begun to work with leaders in Australia, Europe, and the United States as it builds trust and momentum for international evidence-based migrant health.

Vision

CCIRH KEN aims to strengthen primary health systems and improve the quality and delivery of primary healthcare for vulnerable migrant populations. To meet this goal, it will use evidence- and equity-based methods, migrant community engagement, and partnerships with international organizations such as the International Organization of Migration and the Cochrane Collaboration.

Mission

The CCIRH KEN including specialists, primary care practitioners, researchers, policymakers, and immigrant community leaders each dedicated to improving the health of immigrants and refugees. CCIRH KEN is a knowledge translation initiative aimed at improving the health of immigrants and refugees. It is designed to provide practical evidence-based recommendations and high-quality education and community resources to primary care practitioners and medical students, immigrant community champions and health advocates, and health and immigration policymakers.

Examples of CCIRH outputs with public health implications

The Evidence Based Guidelines initiative (Pottie et al. 2011) of the CCIRH was a 6-year interdisciplinary collaboration involving primary care practitioners, specialists, researchers, immigrant community champions, and policymakers that brought an evidence-based lens to the emerging discipline of migrant health. CCIRH produced 20 systematic reviews and formulated 26 evidence-based guidelines for primary care practitioners that covered a broad range of infectious diseases (tuberculosis, HIV, hepatitis B, hepatitis C, varicella, malaria, intestinal parasites, MMR (measles, mumps and rubella), DTP (diphtheria, tetanus, pertussis)), mental health and physical and emotional maltreatment (depression, post-traumatic stress disorder, child maltreatment,

intimate partner violence), chronic non-communicable diseases (diabetes, dental disease, vision disorders, iron deficiency anaemia), and women's health (cervical cancer, unmet contraceptive needs and pregnancy), conditions identified by practitioners across Canada working with immigrants and endorsed by immigrant community champions.

These internationally unique guidelines were made possible thanks to the development of new methods developed by methodologists from the GRADE Working Group, Cochrane Collaboration, and the Canadian Task Force on Preventive Health Care. These methods used an equity–effectiveness approach whereby literature was first synthesized focusing on the PICO question to determine effectiveness (benefits and harms) and then a literature review provided equity consideration to inform the formulation of GRADE recommendations. The equity lens included: Baseline Risk for Population; Culture, Diet, Genetic Differences; Practitioner adherence; Patient adherence (Tugwell et al. 2011).

In an effort to support implementation of the evidence and guideline, CCIRH KEN launched a Knowledge Exchange Website (<http://www.ccirhken.ca>). To introduce student and resident doctors to global health competencies and the CCIRH guidelines, we launched an Open Access Refugees and Global Health e-Learning Program (<http://ccirhken.ca/eLearning>). Currently this programme and its certification quiz are being used in eight universities across Canada and one in the United States to help prepare students to work with vulnerable populations. Most recently, CCIRH KEN has launched its Evidence Based Checklist E-Learning (<http://ccirhken.ca/eLearning>) with Narrative Podcasts and Decision Tables. This open-access evidence-based tool allows practitioners to access the CCIRH-Cochrane Immigrant Health Narrative Podcasts as well as providing a practical checklist for seven world regions. The site also provides an RSS feed targeting evidence-based migrant health news and publication, and a Twitter feed to push out new publications and emerging concerns related to vulnerable migrant populations.

The CCIRH KEN is now initiating Health Impact Assessments (HIAs) to support equity-based improvements in policy, programme, and service design relevant for low-income migrants. This decision support tool will build on previous HIA work, but will be unique in its focus on migrant populations, its implementation of new equity methods, and its link to migrant health methods and data from a new repository emerging from the International Organization for Migration (IOM). This initiative will be initiated in collaboration with decision-maker partners and will aim to promote World Health Assembly priorities on health of migrants: monitoring of migrant health, promote conducive policy and legal frameworks on the health of migrants, promote migrant-inclusive health systems, promote partnerships, networks and multicountry frameworks.

Knowledge translation and global health

Knowledge translation is particularly important for low- and middle-income countries where the burden of disease is much higher and there are less resources for research. For example, INCLEN developed Knowledge Plus Packages in 2003, to focus

on getting evidence into practice and policy. These packages were developed with consideration for equity and effectiveness.

Knowledge translation at the policymaking level: the case of EVIPNet

Low- and middle-income countries have scarce resources to address their health system challenges and need high-quality scientific evidence to use those resources efficiently. If health sector managers and policymakers ignore evidence on the root causes of problems or what works best to address them, they risk wasting precious resources on inadequately designed programmes and policies. The direct consequence of ignoring this evidence is poor population health.

In the last decade, there have been recurrent calls from a number of international organizations for using evidence to strengthen policy and practice. For instance, the WHO in 2004, in its *World Report on Knowledge for Better Health*, mentioned that ‘stronger emphasis should be placed on translating knowledge into action to improve public health by bridging the gap between what is known and what is actually being done’ (WHO 2004). However a number of challenges in this ‘translation’ process have been identified: (1) research evidence competes with many other factors in policymaking, (2) research evidence is not valued enough by policymakers as an information input, (3) research evidence is not relevant to the policy issues that policymakers face, and (4) research evidence is not easy to use (Lavis et al. 2006). Therefore, any initiative aimed to bridge this gap should consider ways to address those challenges in a meaningful and efficient way.

The EVIPNet is an initiative—sponsored by WHO—that promotes the systematic use of health research evidence in policymaking (<http://global.evipnet.org/>). Focusing on low- and middle-income countries, EVIPNet promotes partnerships at the country level between policymakers, researchers, and civil society in order to facilitate both policy development and policy implementation through the use of the best scientific evidence available. EVIPNet comprises networks that bring together country-level teams, which are coordinated at both regional and global levels. The initiative was launched in 2005 and currently includes 38 countries in four WHO Regions (Africa, Americas, Asia, and Eastern Mediterranean) (Hamid et al. 2005; EVIPNet 2008).

EVIPNet activities at the country level are jointly led by local policymakers and researchers and are designed to meet the specific needs of each country. Country activities currently supported under the EVIPNet umbrella include:

- ◆ Production of policy briefs and other user-friendly formats for research synthesis and discussions of policy options.
- ◆ Establishment of priority-setting mechanisms for policy-relevant research syntheses and primary research.
- ◆ Production of research syntheses.
- ◆ Organization of ‘safe haven’ deliberative forums involving policymakers, researchers, and citizens’ groups to stimulate context-specific, evidence-informed local action.
- ◆ Investigation of the potential of clearinghouses, observatories, and rapid response mechanisms that might provide timely, high-quality research syntheses and research relevant to policy.

In addition, at the regional and global levels EVIPNet supports:

- ◆ Capacity strengthening and empowerment of policymakers, researchers, and representatives of civil society to enable them to make better use of evidence in policy-making and advocacy.
- ◆ Interactive learning processes building on experiences to improve evidence-to-policy methods.
- ◆ Monitoring and evaluation processes that document the lessons learned from the use of an array of evidence-to-policy processes in different contexts.
- ◆ Information exchange—disseminating successful methods and tools, experiences, and best practices among partners and other countries, mostly through the EVIPNet Portal—an Internet-based platform, and WHO country offices.

Although it was launched 7 years ago, most of the country teams have only begun implementing different ‘translation’ activities in the last 3 years. Therefore, we cannot yet draw definitive conclusions about what works, in which context and for whom. However, an evaluation team has been collecting data from some of the country initiatives (mostly in Africa) identifying some initial ‘lessons learned’ from the process. (Lavis and Panisset 2010). Strategic alliances and continuous dialogue between policymakers and researchers were considered crucial. Likewise, training and the availability of local technical support in evidence-informed policy-making tools were deemed important facilitators. On the other hand, limited funding and concerns about the sustainability of the initiative at the country level were the most frequently mentioned barriers.

Summing up, the ‘EVIPNet model’ has allowed the development of formal strategies to address some of the challenges in linking evidence to policymaking in low- and middle-income countries, as well as building capacity of both scientists and decision-makers to engage in evidence-informed decision-making. Although it is still too early to assess the impact of this ‘living laboratory’, promising lessons have been identified and will eventually be incorporated in the implementation plans of the different country teams around the world.

Conclusion

In summary:

- ◆ Clinical epidemiology has adopted many public health methods; conversely, it has contributed to methods for tackling public health problems.
- ◆ Clinical epidemiology training has led to many clinicians and other healthcare providers developing research programmes addressing public health problems.
- ◆ Health equity, with a special focus on effectiveness, has recently become a focus of clinical epidemiology, and complements the longstanding concern for this in public health.
- ◆ The equity–effectiveness framework is just one approach for systematically organizing the clinical epidemiological approach to public health problems.
- ◆ Clinical epidemiology has a contribution to make to public health.

Genetic epidemiology

Elizabeth H. Young and Manjinder S. Sandhu

Introduction to genetic epidemiology

What is genetic epidemiology?

Classical epidemiology asks whether, across a study population, a measured exposure is consistently associated with an observed disease or trait. Similarly, *genetic* epidemiology in its simplest paradigm asks whether a *genetic* exposure is associated with a disease or health outcome in a given population. To expand on this, genetic epidemiology can be defined as population-based research that focuses on the aetiological role of genes in the occurrence of disease, in order to provide insights into disease biology and mechanism by unpicking the causal pathway from genes to disease.

Over the last decade there has been an extraordinary pace of change in genetic epidemiology driven by rapid advances in technology. These changes have revolutionized the scope and scale of what can be done, ranging from studies of single gene variants measured in small samples through to the emergence of high-throughput genotyping, genome-wide association studies (GWAS), and next-generation whole-genome sequencing technologies which produce information on millions of genetic variants in thousands of individuals. In parallel, as these genomic technologies provide new opportunities to better understand disease and develop targeted therapeutics for patients, it is becoming increasingly apparent that a knowledge of genomic medicine will be essential for public health practitioners in meeting the public's future healthcare needs.

Genetic epidemiology and public health practice

Ultimately, the goal of genetic epidemiology lies in the application of research findings to clinical care and improved health for the population. The discovery and confirmation of genetic variants associated with diseases and traits may have translational implications—such as advances in treatment and genetic risk prediction. First, the identification of genetic determinants of traits, together with a better understanding of the underlying physiology and regulation, should help inform drug development and improve therapeutic effectiveness. Secondly, in relation to risk prediction, as more disease loci are identified it may be useful to assess whether genetic testing could improve risk prediction of disease beyond traditional risk factors. Additionally, use of genetic data makes risk stratification possible at a young age, when signs and symptoms of disease are not yet present—the clinical and ethical implications of this must be carefully considered. Thus, in this twenty-first-century era of genetic epidemiology

and genomic science, public health practitioners cannot overlook the impact of genetic epidemiology on our understanding of models of disease, individualized medicine, and the relationship between individuals and populations, treatment, and prevention strategies.

Heredity, genetics, and disease

DNA, RNA, and proteins: the structure and function of genes

The human genome carries the chemical information that allows the exact transmission of genetic information from one cell to its daughter cells and from one generation to the next. Our genome is made up of deoxyribonucleic acid (DNA), which consists of a long sequence of nucleotide bases of four types: adenosine (A), cytosine (C), guanine (G), and thymine (T). Strong covalent bonds bind the bases together along a single strand, and weaker hydrogen bonds pair A with T, and C with G, between the two strands in their double-helix form. The double-stranded DNA acts as a template for its own replication: separation of the two strands, and construction of a new complementary strand for each, results in two identical copies of the original.

DNA also acts as a template for its transcription and translation into proteins. The precise order (the 'sequence') in which nucleotide bases are arranged along the DNA strand determines the amino acid sequences of the proteins. First, a single strand of DNA can act as a template for a complementary strand of ribonucleic acid (RNA), through the process of *transcription*. Importantly, in certain regions of DNA, which can be called genes, the transcribed RNA encodes instructions that tell the cell how to assemble amino acids to make proteins through a process known as *translation*. Thus, just as DNA directs the sequence of RNA, so RNA directs the sequence of amino acids and proteins. Only 1–2 per cent of these RNA transcripts encode for protein; the vast majority are transcribed as non-coding RNA which has important biological functions that influence gene expression through a variety of mechanisms (Amaral and Mattick 2008; Kaikkonen et al. 2011).

At its simplest, a *gene* can be thought of as a length of DNA containing the code for the amino acid sequence of a protein. However, few genes exist as continuous coding sequences; rather, most genes contain one or more non-coding regions, called introns, that interrupt the coding regions, or exons. It was previously assumed that non-coding regions of DNA had no biological function. However, we now know that many types of non-coding DNA sequences may have active roles in the regulation of

protein-coding sequences and gene modulation (The ENCODE Project Consortium 2011).

The complete human DNA sequence is the human genome, and contains around 3 billion DNA base pairs. The human genome is distributed among 46 chromosomes, composed of 23 pairs: 22 homologous pairs of autosomes, and one pair of sex chromosomes (X and Y). In each pair of autosomes, one chromosome is inherited from the mother and the other from the father. Chromosomal DNA will contain many genes, with DNA segments of varying length between them. A given gene may exist in alternative forms, differing in DNA sequence, known as *alleles*. The *genotype* of an individual refers to the combination of two alleles inherited (one inherited maternally, the other paternally) at a specific locus—for example, AA, AG, TC, GG, etc. If the alleles are the same, the genotype is homozygous; if different, heterozygous.

Generating genetic diversity

The DNA of the human genome is subject to a variety of different types of genetic variation, defined as any change in the nucleotide sequence or arrangement of DNA. Some genetic variants may have no phenotypic effect and, therefore, no clinical consequences. Other variants will profoundly alter disease susceptibility or, in extreme instances, be incompatible with life.

Genetic variants can be inherited from a parent, or acquired during a person's lifetime (somatic). They may be caused by radiation, viruses, and mutagenic chemicals, as well as errors that occur during meiosis (cell division) or DNA replication, or induced by cellular processes within an organism. Globally, human populations show structured genetic diversity as a result of geographical dispersion, selection and drift (Campbell and Tishkoff 2008; McCarthy et al. 2008; Novembre and Ramachandran 2011). Understanding this genomic variation can provide insights into our human origins and the evolutionary processes that shape variation in phenotypic traits and disease risk.

In the context of genetic epidemiology, we are concerned with understanding how disease susceptibility may be conferred by different kinds of genetic variation. Within an individual, genetic variation can occur at three levels:

- ◆ *Genome variation*: changes that affect the number of intact chromosomes in the cell.
- ◆ *Chromosome variation*: changes that alter the structure of individual chromosomes.
- ◆ *Genetic variation*: changes that alter the sequence of nucleotide bases in a length of DNA.

Genetic variants

Gene variants are alterations in DNA sequence. Different versions of a particular DNA sequence at one specific chromosomal location (locus) are called alleles. When a particular allele is rare—conventionally, with a frequency of less than 1 per cent in the general population—it is known as a *rare variant* or *mutation*. By contrast, where an allele is found in more than 1 per cent of the population it is called a *genetic polymorphism* (literally, 'many forms') or *common variant*. There are many different types of DNA sequence variants, that can range from a change in a single nucleotide base to a change in many thousands of base pairs (Bochud 2012).

The most studied class of variant is the *single nucleotide polymorphism* (SNP, pronounced 'snip'; also known as a point mutation), where the DNA sequence varies in a single base—for example, A is present instead of T, C is present instead of G. SNPs are the most common type of variant; as of June 2012, there are around 38 million known SNPs in the human genome (dbSNP database; National Center for Biotechnology Information n.d.). SNPs lying in protein-coding regions of the gene can alter the code for an amino acid sequence and may (or may not) in turn affect the function or availability of a protein and cause disease. Non-coding SNPs, occurring in intronic (non-coding sequence of a gene) or intergenic (sequence of DNA between genes) regions of the genome can also cause disease, by affecting gene transcription and function. In addition to SNPs, there are also other types of structural variations in the human genome such as variable number tandem repeats (VNTRs), insertions and deletions of DNA bases, and copy number variants (CNVs), which have been used successfully to identify disease genes (Bochud 2012).

Patterns of inheritance, genotypes, and phenotypes

An individual's *genotype* can be understood as the combination of alleles present at a specific position (known as a locus) occupied by a gene on a chromosome. A *phenotype* is an observable, measurable characteristic or trait (biochemical, physiological, morphological, or behavioural) of an individual, other than its genotype. A phenotype could be a quantitative characteristic (such as systolic blood pressure) or a binary disease state (presence or absence of hypertension).

Many variations at the genotype level result in little or no observable variation in phenotype. If, however, a phenotype is present in individuals with just one copy of an abnormal allele, the allele is dominant. By contrast, if the phenotype is only expressed in the presence of two abnormal alleles, the allele is said to be recessive.

Reduced penetrance and variable expressivity are additional factors that influence the phenotypic expression of a particular genetic change. The *penetrance*, or positive predictive value, of a given genotype is the percentage of people with a disease-associated genotype who develop the disease. In cases where all individuals with a particular genotype develop the disease, the gene shows 100 per cent penetrance. In contrast to this, some phenotypes are not expressed in all genotypically predisposed individuals; here, the gene is said to show *reduced penetrance*.

The concept of penetrance is often confused with *variable expressivity*, which is the variation in the severity of expression of a phenotype. Although some genetic disorders exhibit little variation, most have signs and symptoms that differ among affected individuals, in some instances ranging from mild symptoms through to life-threatening complications. Variable expressivity refers to the range of severity of clinical features that occur in different people who have the same genotype.

Single-gene disorders

Single-gene, or monogenic, disorders run in families and are caused by a single mutated gene. Single-gene disorders are often called 'Mendelian' because they display obvious and characteristic patterns of inheritance as described by the nineteenth-century scientist Gregor Mendel, in his study of how traits were passed from

one generation of garden peas to the next. Mendelian disorders are usually characterized by extreme phenotypes in rare patient subgroups that are linked to causal genes with rare mutations. These disorders, whilst individually rare and not contributing substantially to the global burden of disease, might collectively cause significant disease and death in a population. They can also provide invaluable insights into the underlying biology of disease and help to inform the search for susceptibility genes for more common diseases and traits.

Complex multifactorial diseases

Familial aggregation

In contrast to monogenic disorders, genetic disorders may also be complex (also known as multifactorial, or polygenic or non-Mendelian), meaning they are likely to be associated with the effects of multiple genes in combination with lifestyle and environmental factors, with no clear mode of inheritance. Multifactorial disorders include many common diseases such as cancers, heart disease, and diabetes, and quantitative traits such as height, weight, blood pressure and blood chemistries. Patterns of inheritance for complex disorders do not fit simple patterns as with Mendelian diseases. This makes it difficult to determine a person's risk of inheriting or passing on these disorders. Complex disorders are also difficult to study and treat because the specific factors that cause most of these disorders have not yet been identified.

However, this does not mean that the genes cannot eventually be located and studied. Because relatives share a greater proportion of their genes with one another than with unrelated individuals in the population, a primary feature of diseases or traits with a genetic basis is that affected individuals tend to cluster in families. Of course, familial aggregation does not necessarily mean there must be a genetic contribution; family members may develop a disease or trait simply by chance alone, particularly if it is common in the general population, or as a result of a shared environmental exposure. Given this, a helpful measure of familial aggregation is the *recurrence risk ratio* (λ_r), which takes into account the population prevalence of a disease. λ_r estimates the ratio of the risk of developing disease when a relative already has the disease compared to the risk in the general population (i.e. background prevalence).

The correlation of a trait or disease among relatives provides another useful estimate of genetic influence, on the assumption that the degree of similarity in the values of trait (e.g. body mass index (BMI)) measured among relatives is proportional to the number of alleles they share at the loci for that trait. Based on this premise, the more closely related the individuals are in a family the more likely they are to share alleles at loci and—in this instance—the more strongly correlated will be their BMI values. Thus a tendency for BMI to be more similar among relatives than among the general population is further evidence for a genetic aetiology. Familial correlations can also be used to calculate the *heritability* (h^2) of a trait, a measure that quantifies the percentage of phenotypic variation in a trait that is attributable specifically to genotypic differences. The higher the heritability, the greater the contribution of genetic variation among people in causing the variability of a trait for a given population.

Twin studies

To help disentangle the relative contributions of genes and environment in the aetiology of disease, twin and adoption studies are used (Boomsma et al. 2002). Comparison of disease concordance rates in identical (monozygotic (MZ)) and non-identical (dizygotic (DZ)) twins helps to assess the genetic influences on a disease. MZ twins are genetically identical, sharing the same alleles at every locus. DZ twins, on the other hand, share on average half the alleles at all loci, like all siblings. MZ twins provide an opportunity to study disease occurrence when genetic factors are held constant, by measuring concordance in relatives with identical genotypes who may or may not be reared together in the same environment. Concordance in MZ twins in early life can be the result of genes or a shared environment. However, in later life most twins live apart and concordance at that stage may suggest a genetic component to the disease. Concordance less than 100 per cent in MZ twins is strong evidence that non-genetic factors are involved in disease aetiology.

DZ twins reared together provide an opportunity to study disease occurrence when genetic differences are present but environmental factors are shared. Greater concordance in MZ versus DZ twins is strong evidence of a genetic component to the disease. Comparison of concordance rates in MZ versus DZ twins can be used to estimate the heritability of a disease.

As with family studies, twin studies are not without their limitations. First, despite being referred to as 'identical', MZ twins do not have identical gene expression of their identical genotypes; for example, somatic rearrangements will differ between MZ twins, which may give rise to phenotypic discordance and differences in disease susceptibility. Secondly, environmental exposures may not be the same for twins; even the intrauterine environment may differ within a twin pair (e.g. differential placental blood supply in MZ twins). Furthermore, studies comparing MZ to DZ twins are based on the assumption that they differ only by the number of genes they share and that within each pair the exposure to environment factors is identical; yet it is likely that MZ twins share more of their environment than DZ twins (particularly compared to opposite-sex DZ twins). Ascertainment bias poses an additional limitation, where twins who are very alike will tend to participate in studies more than twins who are very discordant for a phenotype. Studies of twins reared apart are easier to conduct than adoption studies, and similarly are an effective way of investigating the influence of shared genes and different environments. However, even with MZ twins separated at birth, intrauterine environmental influences cannot be distinguished from genetic influences.

Adoption studies

Adoption studies provide another valuable source of information about the genetic component of a disease. In this study design, a disease or trait is identified in adoptees and then studied in both their adoptive family (shared environmental factors only) and biological family (shared genetic factors only). Whilst undoubtedly providing the best way of separating out genetic and environmental influences, adoption studies carry obvious difficulties: information may be lacking about the biological family, compounded by their wish not to be identified and approached for details. In addition, relatively small sample sizes for which both adoptive and biological parents are available have limited the use of these studies.

The results of family studies must be interpreted with care. Importantly, familial aggregation of a continuous trait or discrete disease—however measured—does not indicate that genes are wholly responsible. Families share many factors besides their genes, such as common environmental exposures, cultural attitudes, and behaviours. This means that family studies are likely to overestimate the genetic component of a disease, and the strong environmental component to many complex, multifactorial diseases, must not be overlooked.

Role of the environment and gene–environment interactions

Nearly all human diseases originate in large part from a complex interplay between genetic susceptibility factors and modifiable environmental exposures (including chemical, physical, infectious, nutritional, and behavioural factors). Therefore, in understanding the aetiology of disease and assessing the role of susceptibility alleles in disease risk, it is important to examine genetic factors *and* environmental factors and—importantly—the relation between the two: so-called gene–environment interactions.

Studies of gene–environment interactions present a number of methodological challenges (Hunter 2005). The assessment of the relation between genes and environment requires information on both components. Gene–environment interaction may be measured by the different effects of an environmental exposure on disease risk among individuals with different genotypes, or by the different effects of a genotype on disease risk among individuals with different environmental exposures (Yang and Khoury 1997). However, the power of studies to detect statistically relevant interactions is highly dependent on the precision with which genetic and non-genetic exposures are measured. As discussed elsewhere in this chapter, with the advent of next-generation genotyping and sequencing technologies, it is now possible and affordable to generate massive genomic datasets. By contrast, a challenge still remains to achieve accurate and objective measures of environmental exposures such as dietary intake or physical activity that are feasible to collect in a large-scale epidemiological context.

In addition, the need for suitably large sample sizes is a major obstacle to overcome in the design of interaction studies (Hunter 2005). The sample size required to detect the joint effect of two variables is much larger than the size required to evaluate the main effect of each variable; given that many epidemiological studies are underpowered to detect main effects, these studies will be substantially underpowered to detect interactions. Careful consideration of study design, and the accurate and detailed assessment of genetic factors, environmental exposures, and disease phenotypes, is therefore crucial for planning interaction studies that will yield meaningful results.

Determining the details of gene–environment interactions will help us to understand the aetiology of disease and might lead to opportunities for targeted prevention strategies for some high-risk individuals (Hunter 2005; Khoury et al. 2005). Indeed, there may be significant public health benefits in using genetic information to improve existing approaches to identify and modify environmental risk factors, including stratifying the allocation of environmental interventions that prevent disease (Khoury et al. 2005). It may be, for example, that individuals with a certain genotype are particularly susceptible to the negative consequences of specific

lifestyle behaviours, and that they would have most to gain from a targeted preventive intervention programme. Understanding how to detect these individuals and which environmental factors a programme should attempt to manipulate is a major goal of studies that attempt to unravel gene–environment interactions.

Finding disease genes: methods in genetic epidemiology

From monogenic to multifactorial disease

A number of strategies have been used to try and uncover genes involved in the aetiology of common, multifactorial disease (Table 5.12.1). Non-Mendelian disorders may depend on the interplay of common variants—polymorphisms—in several susceptibility genes together with a variable contribution from the environment. These genetic variants are presumed to have only modest effects accounting for a small percentage of variation in a trait, at least when examined individually; however, they may play a more important role through interaction with other gene variants and be responsible for significant population attributable risk for disease.

Linkage studies, fine mapping through mutation screening, and case–control and cohort-based association studies of patients—combined with data from animal models—have uncovered the genes causing many Mendelian, or monogenic, disorders. In turn, a knowledge of the genetic basis of these Mendelian disorders has helped further our understanding of human physiology and played a vital part in establishing the causal role for disease risk factors and in the development of drug targets. In recent years there has been considerable progress in mapping—that is, identifying and localizing—loci that influence susceptibility to common human diseases.

Genetic linkage scans

Linkage analysis is often the first stage in the genetic investigation of a trait, since it can be used to identify broad chromosomal regions of the genome (as opposed to specific alleles) that might contain a disease gene (Teare and Barrett 2005; Altshuler et al. 2008). Genetic linkage is the tendency of genes that are located close to each other on a chromosome to be transmitted together to offspring. Genes that are positioned nearer to each other are less likely to be separated onto different parts of the chromosome during *genetic recombination* (the breakage and rejoining of DNA strands to produce new combinations of alleles, encoding a novel set of genetic information) and are therefore said to be genetically linked. On this basis, susceptibility or causal genes can be localized by searching for genetic markers that co-segregate with the disease trait; if an allele of gene A causes disease, but is otherwise undetectable, whereas the allele of gene B can be easily detected and distinguished, gene B can be used as a marker of the inherited disease. Linkage studies use DNA from family members to identify areas of the genome that show evidence of containing the unknown disease-related genetic variant on the basis of correlation with DNA variation. Polymorphic markers positioned across the genome are genotyped in families, followed by calculating the degree of linkage of the marker to a disease trait. An advantage of linkage analysis is that this approach attempts to map genes purely by position and does not presume any *a priori* hypotheses about their location, biological function, or number.

Table 5.12.1 Common strategies for finding disease genes

Study design	Participants	Strengths	Limitations
Linkage studies	Relatives: large pedigrees, affected sib-pairs, or discordant sib-pairs	Can study multiple genetic markers simultaneously Good for rare traits	Only defines a locus or region, not specific genes
Family-based association studies	Parent–child trios, siblings	Less prone to population stratification Provides a rich context for evaluating shared genetic and environmental influences	Difficult to separate genetic from environmental influences Challenging for outcomes of older age: finding families with more than one affected generation will be difficult Findings may not be applicable to general population
Candidate gene association studies	Unrelated individuals	Powerful study design for common traits	Led by the state of current knowledge: success depends on selecting the right candidate gene
Genome-wide association studies	Unrelated individuals	Genotyping platforms developed to simultaneously examine hundreds of thousands of genetic variants	Lots of false positives; association does not equate to causation Replication of initial results is a challenge
Sequencing studies	Unrelated individuals	Good for identifying rare variants	Limited by costs and existing technological capabilities

Linkage analyses have proved highly successful for finding genes causing Mendelian disorders. However, linkage studies only work well if the phenotype of interest is caused by variation in the same gene region, and have generally been unsuccessful at identifying genes for common disorders where multiple genes are implicated (Hirschhorn and Gajdos 2011). Linkage analyses can only identify large regions and, whilst a very strong candidate gene might exist within the linkage region, such regions may contain hundreds of genes, many of which are biologically plausible candidates. To refine any association may require extensive genotyping—both time-consuming and expensive—and potentially produce many false positive results.

Association studies

Genetic association studies provide an alternative approach to finding disease genes, which overcome some of the limitations of linkage studies. Genetic association studies aim to detect an association between an allele and trait (unlike linkage studies, which focus on a genetic locus as the unit of analysis regardless of the alleles present at that locus). Association differs from linkage in that the same allele (or alleles) is associated with the trait in a similar manner across the whole population, while linkage allows different alleles to be associated with the trait in different families. Whereas linkage studies can only be conducted using family data, association analyses can be done using unrelated and/or related people. Association studies can be conducted at the level of a candidate gene (candidate gene association study), or at the level of the entire genome (GWAS).

Candidate gene association studies

The candidate gene approach has many parallels with identifying and ranking risk factors in an epidemiological study (Tabor et al. 2002): from a large number of potential factors, researchers must pick those factors that are most likely to be associated with the outcome of interest. The selection of candidate genes focuses the search onto specific susceptibility genes that are identified a priori on the basis of their presumed biological relevance to the disease or trait of interest. Once a candidate has been selected, common variants—usually SNPs—in the gene are then identified

(either *de novo* from sequencing/mutation screening, or based on previously published work). The SNPs are then genotyped and tested for association with the outcome of interest. In the case of a binary outcome, SNPs will be genotyped in cases and controls to assess whether the variants are associated with the phenotype of interest; where the outcome of interest is a quantitative trait, SNPs are typed in population cohorts. A strength of this gene-centric method is that it is a highly efficient way of identifying susceptibility genes if biological plausibility is high. Conversely, a drawback of the method is that it is, by definition, limited by the state of current knowledge. Thus countless genes may be overlooked because biological candidacy has not yet been established. Issues of multiple testing and false positives remain limitations of the candidate gene approach.

Genome-wide association studies

GWAS have recently emerged as a powerful new tool for identifying the genetic variants related to common, complex diseases by effectively combining the association and linkage approaches to gene identification (McCarthy et al. 2008; Hirschhorn and Gajdos 2011). The basic paradigm of GWAS is to catalogue thousands of very common SNP markers located throughout the human genome, and then to genotype them in large numbers of unrelated humans who have already been carefully characterized for a wide variety of common diseases and traits. The GWAS approach affords the possibility of exploring the whole genome without any a priori knowledge of underlying disease biology. This allows for hypothesis-free testing of a substantial fraction of common genetic variation for a role in determining disease risk, and potentially enables the discovery of unexpected genetic factors or pathways for common diseases.

A central factor in the development of GWAS is having a comprehensive map of carefully selected SNPs (Box 5.12.1). Over the last two decades, a number of international efforts have successfully done this, creating denser and denser genetic maps. As these have emerged, it has become apparent that many SNPs are strongly correlated (Palmer and Cardon 2005). Consequently, if the pattern of allelic association can be described, direct assay of all existing polymorphisms is unnecessary, because genotypes of

Box 5.12.1 International scientific efforts to describe common human genetic diversity

The Human Genome Project, the SNP Consortium, the International HapMap Project, and the 1000 Genomes Project have collectively identified around 10 million common genetic variants in humans. Knowledge of these SNPs and their patterns of correlation have enabled GWAS which have successfully identified hundreds of novel disease genes (Donnelly 2008; International HapMap 3 Consortium 2010).

Completed in 2003, the *Human Genome Project* was an international collaborative research programme whose goal was to discover all the estimated 20,000–25,000 human genes and map the complete sequence of the 3 billion DNA bases (International Human Genome Mapping Consortium 2001; International Human Genome Sequencing Consortium 2001; International SNP Map Working Group 2001; Roberts et al. 2001; Collins et al. 2003). The official Human Genome Project was meant to have been a 15-year project spanning 1990–2005, but progress was faster than expected. Conducted on an industrial scale at a few large genome centres across the world, genetic maps were developed ahead of the original schedule, and the final stage of large-scale DNA sequencing was facilitated by developments in automated high-throughput sequencing techniques. The need to manage and store the huge amounts of sequencing data that were being produced led to the development of large electronic databases. Importantly, a key aim of this endeavour was to make these genomic data publicly available and accessible to the scientific community at large.

The *SNP Consortium* was established in 1999 as public–private partnership of several companies and institutions to produce a public resource of SNPs in the human genome (Kruglyak 2008). The initial goal was to discover 300,000 SNPs in 2 years, but the final results exceeded this, as 1.4 million SNPs had been released into the public domain at the end of 2001.

The SNP Consortium subsequently joined forces with the *International HapMap Project*. Launched in 2002, the HapMap Project is a global consortium of scientists and researchers with the aim of providing a public resource to inform and accelerate genetic medical research. Specifically, the project set out to describe the common patterns of human DNA sequence variation across the human genome in order to find genes affecting health, disease, and responses to drugs and environmental factors. Whereas the SNP Consortium was concerned with individual SNPs, the HapMap Project focused on examining combinations of SNPs that are inherited together, known as haplotypes. By 2007, the project had genotyped more than 3 million SNPs which captured the majority of all common variants with frequencies above 5 per cent (International HapMap Consortium 2007). In its current phase, ‘HapMap 3’, the project is expanding its scope to identify rarer genetic variants that may be implicated in human disease and achieve a higher resolution map of human genetic variation (International HapMap 3 Consortium 2010).

The *1000 Genomes Project* (1000 G) was launched in 2008 as an extension of the HapMap project. Its aim is to create a public reference database containing an even more detailed characterization of the human genome by extending the catalogue of human genetic variants to include 95 per cent of rarer variants, occurring at frequency of 1–5 per cent (The 1000 Genomes Project Consortium 2010). As of November 2012, using a combination of whole-genome sequencing and exome sequencing, the architecture and functional spectrum of human genetic variation has now been characterized in the genomes of 1092 individuals from 14 populations (The 1000 Genomes Project Consortium 2012).

common SNPs may be inferred from knowledge of only a few representative SNPs. This is the principle underlying the tagging-SNP method: that it is possible to select the maximally informative set of polymorphisms (tagSNPs) to genotype in an association study such that all known SNPs are either directly genotyped or exceed a threshold level of association with a tagSNP. Given the practical limitations on genotyping, selection of tagging SNPs can usefully decrease the amount of genotyping required and thus improve the cost-effectiveness of studies. Inevitably, there is a trade-off between this improved efficiency and the loss of power that occurs when SNPs are discarded. However, by specifying various parameters (e.g. the level of allelic correlation, and the likelihood of genetic linkage) it is possible to try and maximize efficiency whilst maintaining statistical power.

In 2007, the Wellcome Trust Case Control Consortium (WTCCC) set the benchmark for GWAS of common disease on an unparalleled scope and scale. Representing a UK-wide collaboration of more than 50 research groups and 200 scientists in the field of human genetics, the WTCCC genotyped over 500,000 SNPs in DNA samples from 17,000 people across the United Kingdom. Over 2 years, they analysed almost 10 billion pieces of genetic information, and substantially increased the number of genes known to play a role in the development of some of our most common diseases such as heart disease, hypertension, Crohn’s

disease, and diabetes. Many of these genes that have been found are in areas of the genome not previously thought to have been related to the diseases (Wellcome Trust Case Control Consortium 2007). More recently, advances from commercial companies such as Affymetrix and Illumina in the availability of dense genotyping chips with approximately 5 million SNPs are making even larger GWAS both cost-effective and feasible, and there has been considerable progress in the search for disease-related loci and genetic variants using the GWAS approach.

Searching for rare variants

GWAS have now been completed for many common human diseases and related traits, identifying a wealth of common gene variants. However, GWAS have a number of limitations: first, their scope is defined by the current knowledge of existing genetic variants that are included on a specific genotype chip. Second, most of the disease-associated SNPs found in GWAS have very small effect sizes, and explain only a modest fraction of the genetic component of human disease. This is to be expected if much of the missing heritability is due to gene variants that are less common or too rare to be detected by GWAS and have relatively modest effect sizes (Cirulli and Goldstein 2010). On this basis, gene discovery efforts have in recent years expanded to search for rare genetic variants.

To capture such rare variants, it will be necessary to use large sample sizes (thousands of individuals) and sequence entire genomes, rather than genotype a catalogue of variants. Until recently, this was technically unfeasible. However, the technological advances of the last couple of years (so-called next-generation sequencing technology) have made this possible (Metzker 2010; Zhang et al. 2011): now, billions of DNA bases can be sequenced in a matter of days. The most complete study of rare disease variants will require *whole-genome sequencing* in large sample sizes of human participants. At present, despite the rapid pace of technological development and the precipitant fall in the costs, it is likely that the shift to whole-genome sequencing association studies on a massive scale may still not be feasible.

In the meantime, *targeted sequencing* and *exome sequencing* offer more affordable strategies for finding rare genetic variants. Targeted sequencing is focused on genomic regions of specific interest—rather than the whole genome—and enables a systematic assessment of the full spectrum of genetic variation, including common and rare variants, for high-throughput sequencing at a lower cost per sample. Similarly, selectively sequencing only the exome constitutes a powerful and efficient alternative to whole-genome sequencing (Bamshad et al. 2011). Approximately 85 per cent of all disease-causing variants in humans can typically be found in the subset of the human genome that is protein coding—known as the exome. With the availability of next-generation sequencing technology, exome sequencing has become a cost-effective method for the identification of rare sequence variants (Choi et al. 2009; Ng et al. 2009; Pussegoda 2010). This strategy (also known as targeted exome capture) has been used successfully to identify disease-causing variants for a number of rare Mendelian disorders (Choi et al. 2009; Ng et al. 2010; Bamshad et al. 2011) and is an effective technique to detect causal variants associated with disease even when few individuals with disease are sequenced (Cirulli and Goldstein 2010). Although this method has only been used in the study of Mendelian disorders, these studies have provided the framework for the application of this method to the study of complex diseases (Cirulli and Goldstein 2010).

Generating genomic data: analytical issues

At present GWAS typically generate information on several million genetic variants, on many thousands of individuals. Many computational and analytical steps are required to translate massive raw genomic data into usable, high-quality data, and may include techniques for genotype imputation. Imputation is the term used to describe the substitution of some value for missing data. In the context of GWAS data, genotype imputation is the process of predicting or imputing genotypes that are not directly assayed in a study sample of individuals, based on reference panels of SNPs (Li et al. 2009). These *in silico* genotypes can then be used to increase the total number of SNPs that can be analysed for association, thus improving the statistical power of the study. Handling such vast datasets, and identifying the few true association signals amongst the masses of false positive signals, requires extensive computing and storage infrastructure, and advances in computational resources and statistical techniques for processing, analysis, and interpretation (Hunter and Kraft 2007).

A key determinant of the quality in any association study—genetic or non-genetic—is its sample size (Ioannidis et al. 2003).

This is particularly pertinent in genetic studies, which must be powered to detect variants that have only modest associations with the outcome of interest. Small initial studies rarely find the correct result and, even when they do, are likely to overestimate the true effect size (Ioannidis et al. 2003; Lohmueller et al. 2003; Wacholder et al. 2004). An implication of looking at modest effect sizes of genetic variants is the need for sufficiently large sample sizes to avoid underpowered studies with false negative results (Lohmueller et al. 2003; Ioannidis et al. 2006). In addition to ensuring adequate sample sizes, care must be taken to ensure optimal ascertainment of cases and controls, to improve study power—for example, by selecting cases with minimal phenotypic heterogeneity, or focusing on extreme phenotypes such as early-onset severe disease in order to enrich for disease-causing alleles (Hattersley and McCarthy 2005).

Multiple testing is also an issue for these large datasets: when testing so many SNP–disease associations simultaneously, the probability of a nominally significant result from within the entire experiment occurring by chance is higher than the individual *p*-value associated with that result, because of random variation in the data and the large number of tests that are performed (Thomas and Clayton 2004). In other words, there is an increased chance of false positives, and one cannot be certain at the outset whether there are any true associations to be found at all. Consequently, the individual *p*-values of the tests may not be an appropriate guide to actual statistical significance.

There are several statistical techniques which may be used to correct for multiple testing, including a reduction in the number of tests, or the setting of a more stringent *p*-value, or permutation testing (Hirschhorn and Daly 2005). When adjusting for multiple testing, larger samples will be required so that if an initial association is statistically significant, it will remain significant after correction (Benjamini and Hochberg, 1995; Hirschhorn and Daly 2005). Where GWAS findings indicate an association between a genetic variant and a trait or disease, validation and replication studies are essential to determine whether the result of the initial study represents a true reproducible association with genome-wide statistical significance (McCarthy et al. 2008; Ioannidis et al. 2009).

Causal inference

In observational epidemiological studies, causal inferences are potentially susceptible to problems of bias and confounding that, in addition to chance, provide alternative explanations for an observed association between an exposure and a disease. Likewise, the assessment of causality in gene–disease associations is vulnerable to possible other explanations (Geneletti et al. 2011). The role of *bias* must be considered in any observed gene–disease association. In contrast to studies of non-genetic exposures, which are potentially prone to recall bias, an individual's genotype is an exposure that is fixed at conception—thus the association between genetic variants and disease outcomes will not usually be biased in this way. However, a key potential bias in genetic association studies is the differential genotyping of cases and controls. Wherever possible this can be minimized by randomly allocating cases and controls in the genotyping process, so that systematic genotyping errors affecting solely cases or controls are unlikely to occur. Selection bias due to non-comparable cases and controls may also explain the observed associations. Bias, though, need not

necessarily be a problem: it can also be used positively to enhance a study. For instance, one might deliberately select cases enriched for genetic variants (e.g. based on their family history of a disease or trait), in order to improve the power of a study to detect a statistically significant association.

In the context of genetic association studies, classical *confounding* variables such as age and sex are not usually relevant. This is because in order to confound the association between genotype and phenotype, these characteristics would need to be associated with both the genotype and the specific outcome. In the case of genetic association studies this is not applicable, based on the assumption of random assortment—that is, during gamete formation alleles are allocated arbitrarily from parent to offspring independently of other traits. This results in population distributions of genetic variants that are generally independent of behavioural and environmental factors that typically confound epidemiological associations between risk factors and disease.

Nevertheless, we cannot ignore confounding as a result of *undetected population stratification* due to ethnic admixture, which can mimic the signal of association and give rise to false positives and produce associations of disease with genotype at loci that are not linked to any locus that affects disease susceptibility (Hoggart et al. 2003; Freedman et al. 2004; Marchini et al. 2004). Ethnic admixture refers to the presence of multiple subgroups within a larger population, caused by non-random mating, which have differing allele frequencies. This can have implications for studies of gene–disease association if the subgroups have different genotypic distributions (Fig. 5.12.1). If cases and controls are drawn differentially from two or more subpopulations in which marker allele frequencies *and* disease prevalence differ across subpopulations, this will result in an over-representation of one or more genetic subgroups among individuals chosen as disease cases in an association study. In this instance, any SNP with allele proportions that differ between the subgroup and the general population will be associated with disease status. Although the association is real from a statistical point of view, it is regarded as spurious since it does not yield any information about the biology of the phenotype or about the genomic location of the disease-modifying locus; rather, the association between the allele and the disease is confounded by the existence of genetic heterogeneous subpopulations (Wacholder et al. 2000; Ziv and Burchard 2003).

There are a number of different ways of addressing population stratification, such as matching cases and controls according to ethnicity and geographical origin. This matching can be difficult to achieve, and several different control populations might have to be used in any given study. To address this problem, a variety of statistical methods that infer genetic ancestry may be used to control for confounding by population stratification (Cordell and Clayton 2005; Balding 2006; Price et al. 2010). A commonly used statistical method for controlling population stratification is *genomic control*, in which the test statistic is corrected using an inflation factor (λ). To do this, associations between marker loci across the genome and traits or diseases are used to assess population structure and determine an average effect of population structure across the whole genome. The residual effects of stratification for all investigated markers are then adjusted by a uniform λ . Thus the further λ deviates from the value 1, the greater the correction, and the more evidence for presence of population stratification or

other biases; conversely, the closer λ is to 1, the more unlikely it is that stratification is present.

An alternative method is to use *principal components analysis* (PCA) to correct for stratification, which can be carried out using software such as EIGENSTRAT. PCA explicitly models ancestry differences between cases and controls. The resulting genomic correction factor, λ , is specific to a candidate marker's variation in frequency across ancestral populations, minimizing spurious associations while maintaining power to detect true associations. Other approaches include family-based tests such as the transmission disequilibrium test, and mixed models—the latter having the additional advantage of simultaneously addressing population stratification along with other systematic differences, such as family structure or relatedness, that may be present in the data (Price et al. 2010).

Even after many convincing replications of a SNP–disease association, causality may not be inferred; the causal variant may still need to be identified. In this instance, the parallels with classic epidemiology are clear: an association between a SNP and trait might exist if: (1) the SNP with the observed association has a causal role; (2) the SNP has no causal role but is highly correlated (associated) with the true causal variant. It is also possible that the currently identified SNPs might not fully describe genetic diversity, as a result of *incomplete capture of genetic variation*. One therefore cannot exclude the possibility that the unidentified and untyped variants might have shown statistically significant associations with disease and might include among them the true causal variant. Ultimately, to refine the association signal at a locus of interest requires knowledge of the SNP correlations in that region which, in turn, depends on the genetic variation in the region being fully characterized (Ioannidis et al. 2009).

The need for functional validation

For conclusive evidence of causality, the epidemiological approaches just described need to be complemented by efforts to establish which regions of the human genome sequence truly have a biological function and thus may be relevant to disease mechanism and human health. The recent discoveries from genome-wide studies represent a significant advance in our unravelling of the genetic basis of common human disease (Kruglyak 2008). Despite the large number of loci and the robustness of their associations with diseases or disease traits, these loci tend to have small individual effects on phenotype, and even collectively tend to explain only a small fraction of the heritable component. Moreover, it is not yet clear what most of the causal variants or even the causal genes are at these loci. Thus, whether the GWAS approach can yield biologically relevant insights into human physiology remains to be established.

A next step is to identify and validate functional variants through studies of gene expression, in order to clarify the biological role of proteins or other gene products encoded by specific genomic regions and to understand how they influence biological processes and confer disease risk; an example of this is the ENCODE project (Box 5.12.2).

Problematically, some genes may only be expressed locally—for example, in specific brain nuclei—and so attaining samples for physiological studies may prove unfeasible. *In vitro* studies of gene activity, as well as *in vivo* overexpression and knockout studies in experimental animal models, will continue to play an

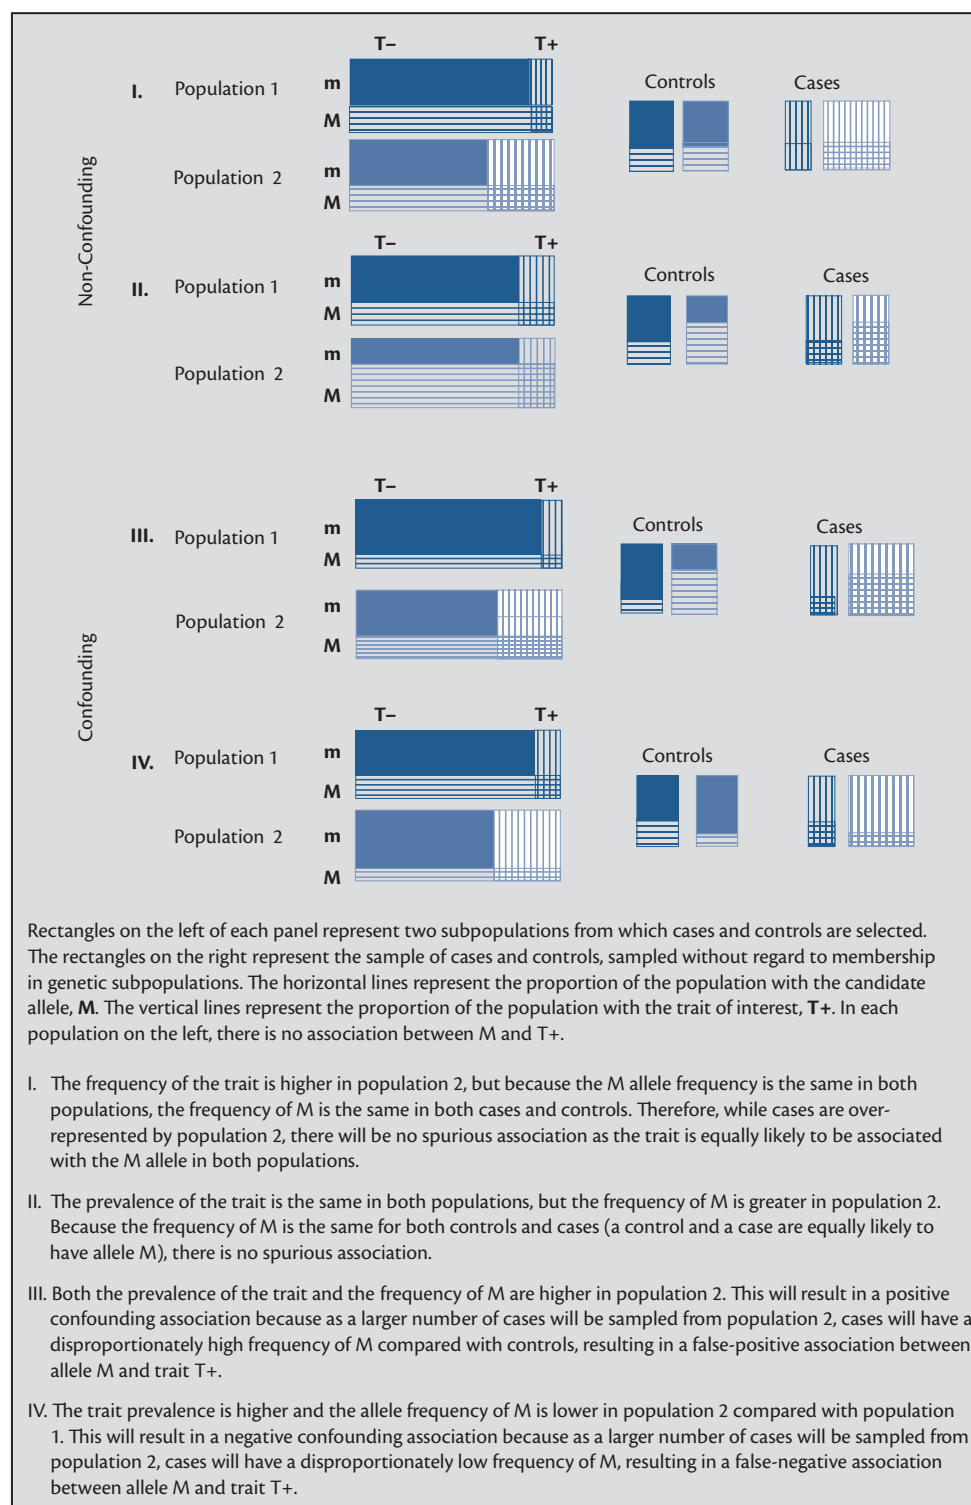

Fig. 5.12.1 Spurious associations as a result of population stratification.

important role in elucidating the specific molecular pathways that are relevant to human physiology and validating GWAS results. If functional studies can confirm a causal role for genetic variants, these results may help identify potential new drug targets.

Using genetic epidemiology to identify new environmental exposures

A key challenge of classical epidemiology is establishing whether an association between an exposure and a disease outcome is

Box 5.12.2 The ENCODE project: identifying functional properties of the human genome sequence

ENCODE, the Encyclopedia of DNA Elements, is an international collective effort to interpret the human genome sequence and make this information available for medical and scientific communities to apply it to understand disease biology and improve human health (The ENCODE Project Consortium 2011). The project aims to define and annotate the functional elements encoded in the human genome sequence, such as those regions that regulate transcription from DNA into RNA, or regulate the expression of genes. In its initial pilot phase in 2003–2007, the ENCODE investigators set out to annotate functional elements in a defined 1 per cent of the human genome. In 2007, the ENCODE project was expanded to study the entire human genome, to locate and describe discrete regions of the genome with a specific biological function. All data and derived results are readily available through a freely accessible public database. In September 2012, the project released an extensive set of results, in 30 papers published simultaneously in several journals, including *Nature*, *Genome Biology*, and *Genome Research*. As part of ENCODE's expansion, a subproject named GENCODE was launched, run by an international team led by the Wellcome Trust Sanger Institute, specifically to annotate the genes within the human genome with even higher accuracy (Harrow et al. 2012).

causal or not. Given the observational nature of epidemiological research, an association may also be completely explained by confounding. In this scenario, the relationship is explained by a third factor that is associated with both the exposure and disease risk; the exposure is not independently or causally linked to disease risk. Epidemiological approaches generally use multivariable statistical analysis to reduce confounding. However, because of residual confounding (as a result of measurement error) and unknown confounders, standard observational epidemiology cannot resolve whether an observed association has a causal basis. The conceptual ambiguity of any disease mechanism (specifically, defining mediators and confounders) also limits statistical modelling to reduce confounding. Furthermore, the observed association may be due to reverse association/causation—that is, the relationship between biomarker and disease could be the result of undiagnosed or early disease rather than the risk factor, and thus a consequence of disease rather than a cause.

Establishing the causal inference of environmental risk factors can be strengthened by the *Mendelian randomization* approach, in which the biology underpinning genetic epidemiology can be exploited to make causal inferences and establish aetiological associations (Davey Smith and Ebrahim 2003; Lawlor et al. 2008; Sandhu et al. 2008). The assignment of alleles from parents to offspring that occurs during gamete formation and conception tends to be random, and not correlated either with environmental exposures or with alleles at other loci. This means that the inheritance of one trait is independent of (that is, randomized with respect to) the inheritance of other traits, and characteristics that may confound any association between an exposure and disease are equally distributed among the relevant genetic variants. Thus the association between a disease and a genetic variant is generally

much less susceptible to reverse causation or confounding by classical or environmental risk factors.

Given this, a comparison of groups of individuals defined by a genetic variant, based on a Mendelian randomization design, is equivalent to a randomized comparison, with only the relevant exposure differing across the relevant genetic variant. Examining the relationship between variants in the genome that show unequivocal associations with the relevant exposure and disease risk is therefore a potential method of assessing whether an exposure might be causally linked to disease (Fig. 5.12.2).

One example of the success of the Mendelian randomization approach is its role in providing evidence of a causal association between lipoprotein(a) and coronary heart disease. Lipoprotein(a) is a composite particle comprising low-density lipoprotein (LDL) cholesterol linked to apolipoprotein(a) and has long been studied as a possible cardiovascular risk factor. Despite large-scale meta-analyses previously demonstrating an association between lipoprotein(a) and disease risk (Emerging Risk Factors Collaboration et al. 2009), it remained unclear whether the observed association reflected a causal relationship or simply an unexplained correlation. However, more recently, a Mendelian randomization study of around 40,000 participants demonstrated that the magnitude of heart attack risk associated with genetically raised concentrations of lipoprotein(a) was consistent with that associated with an equivalent difference in measured lipoprotein(a) levels (Danesh and Erqou 2009; Kamstrup et al. 2009). These findings are consistent with a causal association between lipoprotein(a) and increased risk of heart disease, and highlight lipoprotein(a) as a potential therapeutic target for the management of cardiovascular disease risk. Mendelian randomization analyses have since been used to investigate a number of biomarkers of coronary heart disease—for example, to provide evidence that genetic variants

Fig. 5.12.2 Mendelian randomization. The Mendelian randomization design provides a strategy to help clarify whether there is a causal relation between an exposure and disease. Information on the magnitude of the association between the exposure and disease, A, combined with information on the magnitude of the association between the genetic variant and the exposure, B, is used to estimate the expected magnitude of the association between the genetic variant and disease risk (dashed line in C). Based on several assumptions, including a linear association between the exposure and disease, the direct assessment of C (indicated by the solid line) provides an unconfounded assessment of the association between the exposure and disease risk, A.

underlying triglycerides are likely to be causal and, conversely, to refute a causal role for high-density lipoprotein (HDL) cholesterol in coronary heart disease (Triglyceride Coronary Disease Genetics Consortium and Emerging Risk Factors Collaboration et al. 2010; Voight et al. 2012).

As with all genetic epidemiology studies, there are problems associated with the need for large sample sizes (Ebrahim and Davey Smith 2008). Mendelian randomization studies, like other genetic epidemiological studies, require reliable identification of statistical associations between genetic variants and biomarkers and disease risk. Importantly, the principal requirement is the ability of Mendelian randomization studies to detect an association of equivalent magnitude to that predicted by a proportional change in the relevant trait or risk factor. Given that individual genetic variants are likely to explain only a very small proportion of the variation in a biomarker trait or risk factor, these assessments will require very large sample sizes. Mendelian randomization findings may also be limited by the effects of biological compensation (also known as canalization) and pleiotropy (Davey Smith and Ebrahim 2003; Lawlor et al. 2008). Canalization refers to the process by which potentially disruptive influences on normal development from genetic variations are buffered by compensatory developmental and physiological adaptations. This developmental compensation can lead to inconsistencies in the magnitude of the triangulated associations. Furthermore, the pleiotropic nature (multiple biological and phenotypic effects) of some genetic variants may produce confounded associations between genetic variants and phenotypes. Despite these limitations, Mendelian randomization provides a potential research framework using genetic variants to make causal inferences about modifiable (non-genetic) risk factors for disease and health-related outcomes. These studies, when correctly performed, will provide insights into aetiological mechanisms and causality, informing potential therapeutic and preventative strategies.

Why is genetic epidemiology important for public health?

Genetics has increasingly become an essential part of the epidemiology paradigm. As we have seen, the integration of epidemiological methods with genome-wide technologies has provided unprecedented insights into the aetiology of complex traits and diseases in human populations and has made substantial and independent contributions to the identification of genetic loci

associated with a broad range of complex traits and diseases, including diabetes, heart disease and cancer (Visscher et al. 2012). In parallel, there has been increasing speculation and expectation over how these findings may translate into practical applications for improving human health and lead to public health benefit.

The integration of human genomics discoveries into clinical and public health practice raises a number of questions. Public health is, by its very definition, concerned with improving health from a population perspective (Khoury et al. 2011a, 2011b). How does genomic discovery translate into population health benefit and provide new tools for achieving public health goals? After all, public health prevention and health promotion initiatives have, conventionally, focused on risk factors that are modifiable whereas genetic risk factors are unmodifiable. As we make the case in this section, the discovery and confirmation of genetic variants associated with diseases and traits may have translational implications and major impacts on both individual and population health: first, through elucidation of underlying disease biology and advances in therapeutics and, second, through risk prediction and personalized medicine. In addition, *genetic testing*—undertaken in order to diagnose an inherited disease that is caused by a specific genetic mutation—represents another application of genomic medicine, and is briefly mentioned here for completeness; for a full discussion of the topic, see Chapter 2.5.

Drug discovery and development

The aetiological mechanisms underpinning complex disorders almost certainly involve a combination of many factors: multiple susceptibility genes of modest effect, gene–gene interactions, gene–environment interactions, and heterogeneity of genetic and environmental exposures. The most beneficial application of genetic association studies is likely to be in unravelling the complex biological mechanisms of disease and providing novel insights into disease pathways. In turn, a better understanding of human biology may offer new possibilities for treatment and prevention at the population level (Kingsmore et al. 2008; McCarthy et al. 2008).

Clinical advances in novel therapeutic targets

First, the identification of susceptibility genes for common diseases and traits, together with a better understanding of their underlying functional properties and advances in knowledge of human physiology, should help inform drug development and help determine whether changes in gene activity have pharmacological potential. This is likely to have broad application at the population level (Table 5.12.2). For example, if overexpression of

Table 5.12.2 Examples of matches between GWAS traits and drugs licensed for clinical use

Drug name or class	Gene	Drug indication	GWAS trait
Immunosuppressants and immunomodulators	<i>IL2RA</i>	Relapsing-remitting multiple sclerosis	Multiple sclerosis
Antidiabetic drugs	<i>KCNJ11</i>	Type 2 diabetes	Type 2 diabetes
Statins	<i>HMGCR</i>	Hypercholesterolaemia	LDL cholesterol
Lipid-regulating drugs	<i>LPL</i>	Hyperlipidaemia	HDL cholesterol
Gonadotrophins	<i>FSHR</i>	Female infertility	Polycystic ovary syndrome

a variant gene product was protective against hypercholesterolaemia, then—even if the effect size was small among carriers—a drug which mimicked and inflated the biological effect of the causal variant might be an effective therapy for treatment of raised blood cholesterol. Such a drug could confer clinical benefit across the cholesterol range, and could be used in the general population irrespective of a person's genotype. Such translational opportunities present very real benefits for public health, although expectation must be tempered with realism: the time from gene discovery to an approved and marketable drug takes, on average, at least 10 years. Thus whilst the greatest impact of genomic medicine is likely to result from its application to novel biological pathways and new therapies, the full success of this will only be appreciable in decades to come (Hirschhorn and Gajdos 2011).

Improved responses to existing drug treatments

A second, and more immediate, application of genomic data may be for drug repositioning—that is, the identification or refining of clinical indications for existing drugs (Sanseau et al. 2012). To do this, a first step would be to identify genes that are already being pursued as drug targets and the diseases that these drugs are currently being used to treat. Next, by utilizing data from GWAS, one can see whether those genes may be associated with additional traits or disease, which in turn could be explored as new potential drug indications. As an illustration, denosumab is a drug currently licensed for the treatment of osteoporosis, bone metastases, and rheumatoid arthritis. It acts by targeting the gene *TNFSF11*. In GWAS, the *TNFSF11* gene has been associated with Crohn's disease and thus it is reasonable to speculate that denosumab may have a therapeutic role in the management of Crohn's disease (Sanseau et al. 2012). Taking this approach thus affords translational opportunities for repositioning existing drugs for many common diseases with widespread benefit to public health.

Pharmacogenomics

Patients can vary in their response to prescribed drugs; some patients do not respond at all to certain drug treatments, and for other drugs the dose required to achieve a therapeutic effect can vary (Daly 2010). Personalized treatment for diseases according to genotype might be feasible where risk alleles predict an individual's response to treatment or susceptibility to adverse drug reactions—for example, those genes that influence the effect of coumarin anticoagulant drugs such as warfarin. Warfarin is widely prescribed to reduce blood clotting and is used to protect high-risk patients from stroke, pulmonary embolism, and thrombosis. However, there is a large variation in the dose required to achieve safe yet effective anticoagulation; thus, reducing the uncertainty in establishing the therapeutic dose for individual patients would improve the safety and efficacy of anticoagulation therapy and potentially avoid the clinical complications associated with under- or over-coagulation. Warfarin is metabolized by the hepatic cytochrome P450 enzyme expressed by the *CYP2C9* gene. Its anticoagulant effect is mediated by the enzyme *VKORC1*, which is the target enzyme inhibited by warfarin. Among Caucasians, warfarin dosing is more strongly correlated with genetic variation in the *VKORC1* and *CYP2C9* genes than other patient-related factors (Cooper et al. 2008; Takeuchi et al. 2009; Teichert et al. 2009; Jorgensen et al. 2012). Common variants in *CYP2C9* are associated with slower metabolism of warfarin, higher warfarin concentrations, decreased dose requirements, and susceptibility

to bleeding. Polymorphisms in *VKORC1* lead to hypocoagulable states, and necessitate lower dosage.

The translational applications of these observations are not yet fully established. In principle, an individual's genotype could, potentially, be used as a predictor of warfarin dosage. Indeed, several studies have suggested that combining genetic information on variants in *VKORC1* and *CYP2C9* together with clinical data of a patient may help better predict the warfarin dosage—both for initiation of therapy and for maintenance—required to achieve satisfactory anticoagulation (Hatch et al. 2008; International Warfarin Pharmacogenetics Consortium et al. 2009; Horne et al. 2012; Tatarunas et al. 2012). To date, though, genotype-guided dosing algorithms are not widely used, as they have not yet been shown to be cost-effective in preventing adverse events. However, a number of large clinical trials are now underway, designed specifically to assess whether using genetic data to inform warfarin dosing will improve outcomes for patients being treated with warfarin.

Another example of how genomic information has been successfully applied to understanding drug responses is in the treatment of chronic hepatitis C infection. Standard therapy for the last decade has been a combination of pegylated interferon and ribavirin. It has been well documented that treatment response has only limited efficacy, even for more responsive viral genotypes. However, there is increasing evidence that marked variation in prognosis and response to hepatitis C treatment may be due to differences in human genome diversity; in particular, polymorphisms at the *IL28B* gene locus, encoding interferon- λ -3 (IFN- λ -3), predict response to interferon with genome-wide significance (Ge et al. 2009; Thomas et al. 2009).

A number of other GWAS on pharmacogenomics have identified several novel genetic variants that may affect drug responses or reactions, although many of these associations have failed to reach statistical significance probably due to insufficient sample sizes (Daly 2010). Nevertheless, these findings potentially could be used to develop genetic tests to determine the most appropriate drug for treatment or the optimum dose to prescribe. Whilst it is too early to say if this is of clinical relevance in terms of predicting the trajectory of disease, the prospect of individually tailored treatment in the future raises exciting possibilities—see later for further discussion. Genotype-based randomized controlled clinical trials will be needed to formally evaluate the potential utility of genotype-specific treatment (Manolio et al. 2009; Marteau et al. 2010b).

Risk prediction, stratified medicine, and the emergence of personalized medicine

The emergence of genomic medicine represents a shift from traditional medical genetics—with its focus on rare genetic diseases—towards improved risk prediction and, potentially, greater personalization in the practice of medicine and prevention of common diseases.

Complex diseases and traits—including coronary heart disease, diabetes, hypertension, and most cancers—are caused by multiple genetic and environmental factors. For such conditions, individual risk assessment is an important component of clinical decision-making, potentially identifying people who might benefit from earlier or more intensive interventions. However, individual risk assessment is multifaceted, involving an evaluation of risks and benefits to the individual and to society (British Medical Association Board of Science

2005; Grosse and Khoury 2006). It is also complicated by the debate over statistical methods to assess the utility of risk factors (including genetic variants) for disease risk prediction (Fig. 5.12.3) (Wood and Greenland 2009; Romanens et al. 2010; Talmud et al. 2010). Ultimately—and crucially—the utility of predictive models depends on their ability to alter clinical management which in turn relies on the availability of clinical interventions that are universally indicated but might be beneficial or cost-effective for higher-risk patient subgroups (Hirschhorn and Gajdos 2011).

The identification of several genetic variants, each independently impacting on disease risk, has led to a reassessment of

whether these variants improve risk prediction. To date, genetic variants identified for complex diseases explain only a small proportion of the total variation in disease risk. Accordingly, currently identified genetic susceptibility loci do not have the discriminatory power to substantially improve disease risk prediction (Kraft et al. 2009). However, with large-scale studies and new genomic sequencing technologies, there is the potential to identify new susceptibility loci. Could these variants improve clinical risk prediction? Data indicate that the variation in disease risk explained by many of these unidentified genetic variants may be very small; their detection may always be beyond the resolution of genomic research strategies and

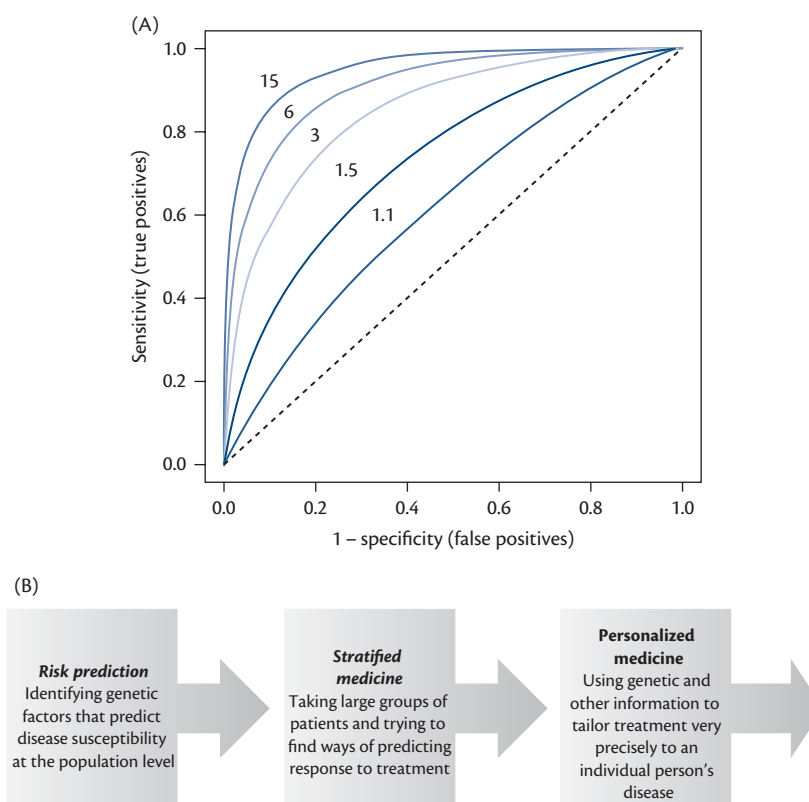

Fig. 5.12.3 Genomic risk prediction and personalized medicine. (A) Individual disease risk prediction from theoretical ROC curves for familial relative risk. Measures of risk discrimination include the sensitivity (the proportion of people who develop disease who were correctly categorized as having a high risk of disease) and specificity (the proportion of people who do not go on to develop disease who were correctly categorized as having a low risk of disease) of the test.

These metrics are usually presented in a receiver operator characteristic (ROC) curve, and an overall assessment is given by the area under the ROC curve. This area is equal to the probability that a random person with disease has a higher value of predicted risk than a random person without disease; thus the larger the area, the better the test.

These metrics can be used to determine the positive predictive value—the proportion of people categorized as high risk that go on to develop disease.

The figure shows ROC curves for various values of FRR. For a given disease prevalence, when the FRR is high (for example, $FRR=15$), the curve rises steeply, indicating the test has a relatively high sensitivity and specificity; the corresponding area under the ROC curve increases. As the FRR drops, sensitivity and specificity fall and the area under the curve decreases. For lower FRRs (for example, $FRR=1.1$), the curve approaches the diagonal dotted line, indicating a test with only 50% probability of correctly predicting risk of disease.

(B) *The spectrum of genomic medicine.* In practice the three elements of risk prediction, stratified medicine, and personalized medicine, are not distinct but form a continuum of patient management. *Genomic risk prediction* involves identifying genetic variants that predict disease risk within a population. Further along the spectrum lies *stratified medicine*, which potentially allows targeting of treatments to specific disease pathways, identification of treatments effective for particular groups of patients, and development of diagnostics to ensure the right patient gets the right treatment at the right time. In the context of genomic medicine, individuals with disease are tested for a genetic marker which indicates whether a patient is likely to show a response to therapy. A further refinement of this approach takes us to *personalized (individualized) medicine*, where patients receive custom-made treatment.

Adapted from *The Lancet*, Volume 376, Issue 9750, Sandhu M. et al., Genomic risk prediction, pp. 1366–67, Copyright © 2010, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/01406736>.

available sample sizes. Hence, a small proportion of the heritability of a disease may not be identified (Clayton 2009; Wray et al. 2010).

At the population level, the familial relative risk (FRR) represents the risk prediction achievable if all relevant loci were identified—assuming that the magnitude of the FRR is accurate and that it primarily reflects shared genetic variants rather than environments (Xu et al. 2009; Wray et al. 2010). With these caveats, for rare or common diseases with greater heritability the discovery of all disease susceptibility variants might provide opportunities to more reliably identify people at greater risk of disease (Fig. 5.12.3). However, for common diseases, such as type 2 diabetes, heart disease, and some cancers, with relatively small FRRs, it is unlikely that the discovery of all susceptibility loci will achieve the necessary predictive accuracy to provide clinically useful information (Wald et al. 1999; Ware 2006; Park et al. 2010).

The ultimate utility of genomic risk prediction in the context of complete genome sequencing will depend on the underlying genetic architecture, the proportion of the variation in disease attributable to genetic factors, and the disease prevalence. Population-wide, it seems unlikely that genomic risk prediction alone will attain the discriminatory resolution to predict individual disease-risk for many common diseases with only modest heritability. However, the use of genomic factors for individual disease risk prediction in conjunction with conventional risk factors, or for identifying subgroups for screening, remains unclear (Pharoah et al. 2008; Xu et al. 2009). Whilst at present we lack the ability to provide clinically useful risk prediction, as more disease loci are identified it may be beneficial to re-assess whether genetic testing could improve risk prediction of common disease beyond traditional risk factors.

In addition to risk prediction and a better understanding of disease aetiology, genetic data may be increasingly used in the field of stratified medicine (Fig. 5.12.3). Patient response to drug treatments and therapeutic interventions varies markedly across the population as a result of differing underlying mechanisms of disease and patient responses to both disease and treatment. Stratified medicine can be described as identifying the different strata within a disease using a biomarker or genotype, in order to identify a patient subpopulation which is more likely to benefit or experience an adverse reaction in response to a given therapy. This approach—with patients better matched to therapies—is anticipated to have a major effect on both clinical practice and the development of new drugs and diagnostics (Trusheim et al. 2007). At the extreme of this patient matching are ‘personalized’ medicines, which by definition vary for each individual’s unique genetic make-up, such as customized stem-cell based therapies. However, the logistical, clinical and ethical implications of this must be carefully considered.

Limitations and challenges of genetic epidemiology

Human genetics has advanced at an extraordinary pace during the last 20 years. The number of, and the ease with which, genetic markers of disease are being discovered has gone from dozens to millions. As we enter the era of next-generation high-throughput genotyping and sequencing, it is important to remember the limitations of this

knowledge in order to have realistic expectations of what it can, and cannot, deliver and to apply it appropriately and responsibly.

Ethical, legal, and social implications

The generation of genetic information has contributed greatly to our understanding of the molecular basis of disease and, increasingly, to the development of effective treatments. In parallel, there are concerns about the ethical, legal, and social implications of this knowledge on the well-being of individuals and populations (Box 5.12.3).

Accounting for unexplained variation

Despite the success of GWAS in identifying disease genes, a substantial proportion of the heritability of disease traits remains unexplained (Manolio et al. 2009). So far, loci shown to be associated with disease only account for a small fraction of the total genetic contribution; the great majority of susceptibility loci remain to be identified. How do we account for this remaining variation? Unexplained heritability may be due to unknown common variants of small effect, or rare variants with larger effects, or influences by environmental factors. To better understand the missing heritability of disease traits, larger-scale studies are required, using denser SNP arrays. In addition, exome sequencing, whole genome sequencing, or whole genome association studies in large populations will be needed to identify all potential variants within a gene or locus. Sequencing candidate genes in individuals at the extremes of a quantitative trait (e.g. the extremes of lipid levels) may identify new variants, common or rare, and help further our understanding of disease biology and prevention.

Genetic epidemiology in low- and middle-income countries

To date, most human genomics research has been done in populations of European ancestry, and has successfully provided new insights into the biology of chronic diseases and their risk factors in these populations. However, the relevance of many recent genomic findings to populations in low- and middle-income countries (LMICs) is not known. It may be difficult to meaningfully apply the findings from Western populations to LMIC populations, where both genetic and non-genetic susceptibility may be different.

To fully appreciate the impact of a genetic variant on disease risk it will be important to establish whether the findings from one population apply to other populations of different ancestry. Globally, human populations show structured genetic diversity as a result of geographical dispersion, selection and drift (Campbell and Tishkoff 2008; Novembre and Ramachandran 2011). Accordingly, among many populations in LMICs there is marked genomic diversity—in particular, among populations of African descent, where there is more human genetic diversity than anywhere else (Tishkoff et al. 2009). Given this, understanding the genomic basis of common diseases and their risk factors in LMICs is likely to provide additional insights into disease aetiology and potential therapeutic strategies (Hill 2006; Campbell and Tishkoff 2008; Novembre and Ramachandran 2011).

Thus the value of GWAS will be enhanced further by including populations with greater genetic diversity and less correlation between variants, and will benefit from more precise

Box 5.12.3 Examples of some of the ethical, legal, and social implications of genetic epidemiology**Genetic discrimination**

A primary concern is that genetic information could be harmful and could lead to discrimination such as: (1) denial of health insurance or employment, based on genetic susceptibility; and (2) stigmatization of a specific ethnic group.

Genetic determinism

This stems from a misconception about the causal relationship between genetics and behaviour, and the erroneous belief that genetic information is somehow more predictive and certain than other types of health information because ‘you cannot change your genes’. This can lead to an unhelpful and inaccurate sense of inevitability and the use of genetic determinism to explain health disparities.

Data protection

The generation of vast amounts of genetic data, and its potential identifiability of individuals, raises significant issues around the storage of genetic data, data processing, data access, and confidentiality. Additional concerns exist around sharing sensitive data with other family members, such as in the context of reproductive choice.

Return of individual research findings (including incidental findings)

Disclosing study results and presenting clinical risk information can have important effects on health outcomes and health behaviours among study participants. Understanding probability information about disease risk and the benefits of intervention is a vital component of an individual’s decision-making capacity. The obligation of the health professional to return genetic findings—particularly when the clinical validity and utility is unclear—needs to be considered. Additionally, disclosing results for which treatments may be unavailable or prohibitively expensive raises particular ethical issues.

Informed consent

National and international research guidelines agree that valid consent to participate in research must be consent that is informed in a manner that is linguistically and culturally appropriate and is understood by the study participant. This can be particularly challenging in the context of genomics research which is complex and often difficult to understand, and where the implications of research findings are largely unknown (including incidental findings which are not relevant to the original research question but may have clinical significance). An additional challenge is to resolve issues around individual consent versus family consent, including the right ‘not to know’ the findings of genetic studies.

Fair distribution of benefits from research

As with all fields of research, particular individuals, groups, or communities should neither bear an unfair share of the direct burdens of participating in research, nor should they be unfairly excluded from the potential benefits of research participation. This is particularly pertinent when genetic research is conducted in countries where genetic services are not available or may not be readily accessed. Inclusiveness in genetic research and fair distribution of benefits and burdens should be important considerations for researchers, research ethics boards, and sponsors. Issues of fair and equitable treatment arise in deciding whether and how to include individuals, groups or communities in research, and the basis for the exclusion of some.

characterization of phenotypes and environmental exposures (Manolio et al. 2009). Ultimately, large-scale international collaborations will facilitate studies in different global populations and help to determine whether loci identified in initial GWAS (usually done in populations of European ancestry) are relevant in non-European individuals. As a result of such studies, our ability to treat disease and reduce risk will be much more complete.

In addition to studies of the human genome, techniques from genetic epidemiology can also be used to examine pathogen genomes, yielding important applications for human health—for example, in helping to understand the causes of resistance to malaria treatment. First-line treatment for uncomplicated falciparum malaria is artemisinin-based combination therapy (ACT), which has been highly effective in treating this disease. However, in recent years, resistance to artemisinin has become increasingly prevalent in Cambodia and Thailand, characterized by slow parasite clearance from the blood (Uhlemann and

Fidock 2012). Antimalarial drug resistance hinders malaria control and is a major public health threat to global initiatives to control and eliminate the disease. Using a variety of techniques, including targeted association studies of candidate genes for ACT and genotyping of variants across the malaria genome, a number of studies have identified that resistance to artemisinins is, in part, genetically determined by variants in the malaria-parasite genome and conclude that parasite genetics have a central role in determining parasite clearance rates (Cheeseman et al. 2012; Phyo et al. 2012). Furthermore, these studies report that the heritability (h^2)—that is, the contribution of parasite genetics that explains the variation in parasite clearance—has increased from 30 per cent in 2001–2004 to 66 per cent in 2007–2010 (Phyo et al. 2012). The mechanisms underlying the reported associations are not yet known, but understanding these biological processes could potentially inform new approaches for effective malaria treatment in the future.

The application of genetic epidemiology and genomic research to public health practice merits specific discussion in the context of LMICs—where the global burden of infectious and chronic, complex diseases is greatest. Additionally, in LMICs healthcare is often severely constrained by limited financial and human resources and a lack of appropriate infrastructure (Burke et al. 2010). It would be simplistic to suggest that because of the great health needs of LMICs—overwhelmingly determined by economic and social factors—genomics is an irrelevance and has no role to play in improving health. Rather, to omit genomic discoveries from the healthcare agenda of LMICs would serve only to promote existing inequities between rich and poor, between economically advantaged and disadvantaged. Public health professionals have an essential role to play in leading the response to genomic medicine in LMICs, ensuring that healthcare providers and policymakers are informed by a strong evidence base for the effectiveness of genomic approaches in improving population health.

Improving phenotypic characterization and classification of disease

Associations between genetic variants and phenotypes are limited by the accuracy with which each is measured. The ability to measure genotypes now far exceeds our ability to measure phenotypes (Altshuler et al. 2008). We need to match this with more detailed, and more accurate, assessments of clinical phenotypes. Indeed, carefully designed GWAS with thorough phenotypic characterization have the potential to redefine disease classification (Kingsmore et al. 2008). In some cases, it will become increasingly possible to unpick the phenotypic complexity of diseases that involve several pathological processes and allow us to establish whether genetic factors distinctly contribute to different phenotypes of the condition. A recent example of this is in the area of coronary artery disease (CAD), where GWAS have successfully discriminated genetic variants for distinct CAD phenotypes—suggestive of distinct underlying pathological mechanisms (Reilly et al. 2011). This opens up avenues for patient stratification and personalized treatments.

Conversely, for other complex diseases that have previously been regarded as distinct clinical entities, GWAS findings may point to common underlying disease processes and a shared pathogenesis. To illustrate, a recent GWAS of Crohn's disease and ulcerative colitis found a sizeable overlap in susceptibility loci for the two diseases. With such a degree of sharing of genetic risk, it seems likely that many of the biological mechanisms involved in one disease have some other role in the other (Jostins et al. 2012). These studies provide a rich source of clues to the biological mechanism underlying complex disease. However, the translation of such GWAS discoveries into prognostic and therapeutic benefit will need greater insights into the relation between each loci and the different phenotypes.

Risk communication

The extent to which genetic information will play a role in 'personalized medicine' will depend not only on whether predictive accuracy beyond conventional measure can be attained, but also on whether there are interventions whose effectiveness is improved by knowledge of a genetic result. A key challenge will therefore be to find effective ways to communicate information

on small incremental risk increases conferred by genetic markers for disease risk, in order to prompt changes in lifestyle that will ultimately confer health gain to individuals. At present, it is not clear if personal genomic information is likely to beneficially impact public health through motivation of lifestyle behavioural change. Risk perception and risk communication are complex processes, and are shaped by social and cultural values, assumptions, and beliefs held at the individual and societal level.

An individual's ability to make sense of genetic information will involve an understanding of the concepts of genes, genetics, ancestry and heritability, in a manner that is culturally relevant and acceptable. Most of the information we have on genetic susceptibility to disease is, at best, incomplete as discussed earlier in this chapter; health professionals' advice to people will have to change as more robust evidence on risk factors comes to light, sometimes seeming to conflict with, or even to contradict, previous knowledge. Conveying this uncertainty is a difficult and challenging task.

The creation of personal genomic risk profiles, that predict an individual's lifetime risk of various common diseases, raises the possibility that public health promotion could potentially be directed at susceptible individuals/groups of people in the population based on their genomic risk profile. This marks a departure from conventional public health practice which has tended to focus on social and environmental determinants of disease and health, and allows a focus on preventing disease, disability and mortality among people with specific genotypes that increase their disease risk. It is tempting to think that knowledge of individual risk of a given disease, as predicted by genome-wide profiling, will motivate individuals to change their behaviour and promote greater adherence to a healthy lifestyle or treatment regimen in order to reduce their risk; however, human behaviour is complex and risk estimates are difficult to communicate meaningfully to patients (Loos 2011). Recent studies, including a Cochrane review, seem to indicate that genetic testing may not result in individuals changing their behaviour in any significant or sustained way (Marteau et al. 2010a; Bloss et al. 2011).

Conclusions

It is clear that public health practice cannot ignore the impact of genetic epidemiology and the knowledge derived from genomics research. The results from genetic epidemiological research have two broad translational applications which have the potential to contribute to population health and well-being. First, as our understanding of disease aetiology and its underlying biological mechanisms increases, there is the potential for new drug development and improved therapeutic strategies to manage disease. Second, in parallel, there is growing interest in the use of these genetic variants to predict individual disease risk over and above classical risk factors, and to develop stratified and personalized approaches to diagnosis and disease management. The public health community has a central leadership role to play in critically and systematically evaluating these discoveries for their potential use in disease prediction, prevention, and treatment response. Furthermore, public health practice must ensure that the benefits of genomics are applied with equity across the population.

As our understanding of the molecular basis of disease increases, there is a need for public health practitioners to have a degree of knowledge about genetic susceptibility and to understand the scientific basis of genetic epidemiology and the benefits it can afford, as well as to be aware of the limitations of this knowledge. The ultimate goal of public health is to promote and improve the health and well-being of the population. A public health approach to genetic epidemiology should assess the contribution of genomics to health in the context of wider determinants of disease and health, and provide a robust evidence-base to inform healthcare policymakers, health service commissioners, and providers.

Validity and bias in epidemiological research

Sander Greenland and Tyler J. VanderWeele

Introduction to validity and bias in epidemiological research

Some of the major concepts of validity and bias in epidemiological research are outlined in this chapter. The contents are organized in four main sections: validity in statistical interpretation, validity in prediction problems, validity in causal inference, and special validity problems in case-control and retrospective cohort studies. Familiarity with the basics of epidemiological study design and a number of terms of epidemiological theory, among them risk, competing risks, average risk, population at risk, and rate, is assumed. A number of textbooks provide more background and depth than can be given here; see, for example, Kelsey et al. (1996), Koepsell and Weiss (2003), Checkoway et al. (2004), and Rothman et al. (2008).

Despite similarities, there is considerable diversity and conflict among the classification schemes and terminologies employed in various textbooks. This diversity reflects that there is no unique way of classifying validity conditions, biases, and errors. It follows that the classification schemes employed here and elsewhere should not be regarded as anything more than convenient frameworks for organizing discussions of validity and bias in epidemiological inference. Many types of bias can be qualitatively illustrated with causal diagrams, which reveal the relationships among confounding and selection bias; for example, see Greenland et al. (1999), Cole and Hernán (2002), Hernán et al. (2004), Glymour and Greenland (2008), and Pearl (2009).

Several important study designs, including randomized trials, prevalence (cross-sectional) studies, and ecological studies, are not discussed in this chapter. Such studies require consideration of the validity conditions mentioned earlier and also require special considerations of their own. Further details of these and other designs can be found in the general textbooks cited in the preceding paragraphs. For discussions of the problems of ecological studies, see Greenland (2001, 2002a, 2004a) and Morgenstern (2008). Meta-analytic methods are discussed by Eddy et al. (1992), Greenland and O'Rourke (2008), and Borenstein et al. (2009). A number of central problems of epidemiological inference are also not covered, including choice of effect measures, problems of induction, and causal modelling. For critical discussions of effect measures by the present authors, see Greenland et al. (1986, 1991, 1999), Greenland (1987, 1999, 2002b), Greenland and Robins (1988), Rothman et al. (2008, chapter 4), and VanderWeele (2012).

Greenland (1998a, 1998b) and Rothman et al. (2008, chapter 2) discuss problems of inductive and probabilistic inference, Greenland and Brumback (2002) review causal modelling in epidemiology, and Rothman et al. (2008, chapter 2) discuss broader issues in causal inference and philosophy.

Among the deeper problems not discussed here are the failure of conventional statistical methods to account for non-random sources of uncertainty, and the tendency of people (including scientists) to make overconfident and biased inferences in the face of uncertainty (Gilovich et al. 2002). Analytical approaches to these problems are discussed by Eddy et al. (1992), Greenland (2005), Greenland and Lash (2008), and Lash et al. (2009, 2014).

Inference and validity

Epidemiological inference is the process of drawing inferences from epidemiological data, such as prediction of disease patterns or identification of causes of diseases or epidemics. These inferences must often be made without the benefits of direct experimental evidence or established theory about disease aetiology. Consider the problem of predicting the risk and incubation (induction) time for acquired immunodeficiency syndrome (AIDS) among persons infected with type 1 human immunodeficiency virus (HIV-1). Unlike an experiment, in which the exposure is administered by the investigator, the date of HIV-1 infection cannot be accurately estimated in most cases; furthermore, the mechanism by which 'silent' HIV-1 infection progresses to AIDS is not known with certainty. Nevertheless, some prediction must be made from the available data if one is to prepare effectively for future healthcare needs.

As another example, consider the problem of estimating how much excess risk of coronary heart disease (if any) is produced by coffee drinking. Unlike an experimental exposure, coffee drinking is self-selected; it appears that persons who drink coffee are more likely to smoke than non-drinkers and probably tend to differ in many other behaviours as well (Greenland 1993). As a result, even if coffee use is harmless, we should not expect to observe the same pattern of heart disease in users and non-users. Thus, small effects of coffee drinking are very difficult to disentangle from the effects of other behaviours. Nevertheless, because of the high prevalence of coffee use and the high incidence of heart disease, any effect of coffee on heart disease risk may be of considerable public health importance.

In both these examples, and in general, inferences will depend on evaluating the validity of the available studies; that is, the degree to which the studies meet basic logical criteria for absence of bias. When (as is usually the case) aspects of validity cannot be guaranteed by successful design strategies, such as blinded random assignment (which ensures that baseline non-comparability is random), we must evaluate the magnitude of bias that would arise from plausible violations of validity conditions.

Because biases due to misinterpretation of statistics are often neglected in textbooks yet pervade the health-sciences literature, the next subsection will describe common misinterpretations to be alert for when examining reports or analysing data. The remaining subsections will outline and illustrate major concepts of validity and bias in epidemiological research as applied in three settings: prediction from one population to another, causal inference from cohort studies, and causal inference from case-control and retrospective cohort studies. Parallel aspects of each application will be emphasized. In particular, each problem requires the consideration of comparison bias (better known as confounding), follow-up bias (i.e. loss-to-follow-up or censoring bias), bias due to mismeasurement, bias due to erroneous statistical models, and bias due to erroneous statistical interpretation. (The term 'bias' is, here, used in the informal epidemiological sense, and corresponds to the formal statistical concept of inconsistency.) Case-control studies require the additional consideration of case-selection bias and control-selection bias, and are often subject to additional sources of measurement error beyond those occurring in prospective cohort studies. Similar problems arise in retrospective cohort studies.

Misinterpretations of statistics

Severe consequences can arise from failure to properly interpret statistical outputs, and failure to recognize when the output is the result of a statistical method breaking down. Unfortunately, few textbooks discuss these problems in detail, even though they can result in inferential errors as severe as those from the more familiar biases discussed in the following subsections.

Two problems very common in the health-sciences literature are briefly described here. Both problems as well as many others can be avoided with certain Bayesian statistical approaches. Detailed arguments for Bayesian approaches can be found in Berger and Berry (1988), Greenland (1998b, 2006), and Thomas et al. (2007). For an introduction to Bayesian methods that can be carried out with ordinary software, see Greenland (2007) and Sullivan and Greenland (2013). The remainder of this subsection concerns only conventional 'frequentist' methods of significance tests, confidence intervals (CIs), *p*-values, and model fitting.

Misinterpretations of statistical significance

Many authors have noted that significance testing is very difficult to interpret correctly, so difficult that otherwise expert epidemiologists and even statisticians routinely make dramatic mistakes (Altman et al. 2000; Greenland 2004b, 2011, 2012a; Greenland and Poole 2011). Perhaps the largest source of misreporting and misjudgement in the scientific literature, however, is the simple confusion of presence or absence of an association with presence or absence of statistical significance (Altman and Bland 1995; Rothman et al. 2008, chapter 10; Greenland 2011). A common

consequence of this confusion is the mistaken reporting of non-significant results as 'confirming' the null, when in reality the results are completely ambiguous. For example, a study that results in 95 per cent confidence limits for a relative risk (RR) of 0.80 and 2.0 is non-significant. Even if perfectly valid, however, it would not support the null hypothesis any more than it would support the hypothesis that the true relative risk is 1.5 (a 50 per cent increase in risk). Misinterpreting non-significant results as null is easily avoided by paying attention to the confidence limits (Rothman 1978; Altman et al. 2000; Poole, 2001; Rothman et al. 2008, chapter 10). The limits of 0.80 and 2.0 show that the results are not 'significantly' different at the 0.05 level from any relative risk between 0.80 and 2.0. Unfortunately, mistaken claims that non-significant results support the null hypothesis of no association still pervade the field, especially in important policy and legal applications of statistics to epidemiology (Greenland 2004b, 2011, 2012a; Greenland and Poole 2011).

A converse misinterpretation is to say that two groups showed different results because they had different statistical significance. As an example, one article abstract (Park et al. 2007) reported that an inverse association with colorectal cancer was 'seen for total vitamin D intake in men (RR = 0.72, 95 per cent CI: 0.51, 1.00; *p* for trend = 0.03) but not in women' (the estimate compares the highest quintile of vitamin D intake to the lowest). Examination of table 3 of the paper reveals, however, that the corresponding relative risk for women was 0.89 with 95 per cent confidence limits of 0.63 and 1.27, which means that the association for women was in fact inverse, just as in men (0.89 = 11 per cent lower risk in the highest quintile than in the lowest). Although it was not significantly different at the 0.05 level from 1 (the null), it was also not significantly different from the relative risk of 0.72 seen for men; nor was it significantly different from any relative risk from 0.63 to 1.27. One way to summarize these results would have been to state that an inverse association was observed in both men and women, but that it was weaker and non-significant for women. An even better interpretation is that the study had too few subjects to detect whether men and women actually differ with respect to the relation of vitamin D to colorectal cancer. Such honest reports of study weaknesses are not common, however. This issue is especially problematic in the interpretation of subgroup analyses in randomized trials (Rothwell 2005; Wang et al. 2007).

An opposite misinterpretation of the one just illustrated is to claim that two results are not significantly different because their confidence intervals overlap. It is true that they will not be significantly different if the interval from either group contains the point estimate from the other group (as in the preceding example, in which the men's point estimate of 0.72 falls within the women's limits of 0.63 and 1.27), and that the two groups will be significantly different if their confidence intervals do not overlap. Nonetheless, if the intervals overlap but neither interval contains both point estimates, one cannot determine significance without conducting a direct test of the difference in results.

Misinterpretations such as just described arise in part from the conventional use of a cut-off value such as 0.05 to declare presence or absence of significance, and the corresponding use of 95 per cent to determine the width of a confidence interval (which is just the collection of all values that are not significant at the 0.05 level). In reality, there is a continuum of degrees of significance, as measured by the *p*-value ('significance level'), and any cut-off value is

both arbitrary and distortive (Rothman et al. 2008, chapter 10). Thus, some authors have encouraged a movement away from classifying associations ‘significant’ or ‘non-significant’, towards presenting instead the actual p -value for the tested hypothesis and for other values of interest (see Poole 1987a, 1987b; Goodman 1993; Greenland and Poole 2013a, 2013b).

Even if one presents p -values, however, the complexities and subtleties of determining and interpreting significance become even worse when multiple tests are involved (the ‘multiple comparisons’ problem). Here, adjustments for the multiplicity of tests can worsen certain problems even as they address others, for example, by worsening power even as it protects the validity (alpha level) of the tests. They may also shift the null hypothesis being tested to one that, if understood, might be seen as irrelevant to the scientific question at hand. For a discussion of these issues and further references, see Rothman et al. (2008, chapter 10) and Greenland and Poole (2011). Many of these problems can be avoided by shifting to a multilevel (hierarchical) approach for the analysis (Greenland 2000a, 2000b).

Sparse-data bias

Most epidemiological studies collect data on so many variables that any thorough stratification (tabulation) of the data on those variables will result in ‘sparse data’, in which many if not most cell counts may be very small. Classical epidemiological methods such as standardization break down in the face of this sparsity. Although modelling was developed to address problems of sparse data, it is not a sure fix. Conventional methods for fitting risk and rate models such as maximum likelihood (ML), weighted least squares, and generalized estimating equations are ‘large-sample’ (asymptotic) techniques, meaning that they have sample-size requirements for valid performance. In the context of say logistic regression (the most common method in epidemiology), this means that among other things there are sufficient numbers of cases and non-cases observed at all levels of categorical variables in the model.

A serious problem is that when there are too few cases or non-cases in a given category a coefficient estimate based on that category may ‘blow up’, taking on a value that is much too large in absolute magnitude. This problem can arise in both unconditional and conditional logistic regression (Greenland et al. 2000). In a similar fashion, certain estimates may become inflated when there are too many variables in the model relative to the number of cases and non-cases. This hazard is especially severe when the data are divided into subgroups for separate analysis, for example, separating men and women instead of modelling effects with a variable for gender, or when ‘interaction’ (product) terms are used in the model. In almost all reports, the inflated estimates if ‘statistically significant’ are misinterpreted as representing strong effects rather than being recognized as statistical artefacts.

To spot these problems, investigators should check tables of the variables in the model against the outcome, and beware of estimates obtained when the observed numbers in each category fall below 4 or 5, or when the ratios of the number of cases and non-cases to the number of variables in the model fall below 4 or 5. Various methods for shrinkage estimation (including random-coefficient, hierarchical, multilevel, ridge, penalized, and Bayesian regression) can be used as an alternative to collapsing categories or deleting variables from the model to avoid

sparse-data bias (Greenland 2000b, 2007; Sullivan and Greenland 2013).

Validity and bias in prediction problems

Turning now to more traditional topics, the following prediction problem will be used to illustrate several basic concepts of validity. A health clinic for homosexual men is about to begin enrolling HIV-1-negative men in an unrestricted programme that will involve retesting each participant for HIV-1 antibodies at 6-month intervals. We can expect that, in the course of the programme, many participants will seroconvert to positive HIV-1 status. Such participants will invariably ask difficult questions, such as: What are my chances of developing AIDS over the next 5 years? How many years do I have before I develop AIDS? In attempting to answer these questions, it will be convenient to refer to such participants (i.e. those who seroconvert) as the target cohort. Even though membership of this cohort is not determined in advance, it will be the target of our predictions. It will also be convenient to refer to the time from HIV-1 infection until the onset of clinical AIDS as the AIDS incubation time. We could provide reasonable answers to a participant’s questions if we could accurately predict AIDS incubation times, although we would also have to estimate the time elapsed between infection and the first positive test.

There might be someone who responds to the questions posed here with the following anecdote: ‘I’ve known several men just like the ones in this cohort, and they all developed AIDS within 5 years after a positive HIV-1 test.’ No trained scientist would conclude from this anecdote that all or most of the target cohort will develop AIDS within 5 years of seroconversion. Of course, one reason is that the men in the anecdote cannot be ‘just like’ men in our cohort in every respect: they may have been older or younger when they were infected; they may have experienced a greater degree of stress following their infection; they may have been heavier smokers, drinkers, or drug users; and so on. In other words, we know that the anecdotal men and their post-infection life events could not have been exactly the same as the men in our target cohort with respect to all factors that affect AIDS incubation time, including measured, unmeasured, and unknown factors. Furthermore, it may be that some or all of the men referred to in the anecdote had been infected long before they were first tested, so that (unlike men in our target cohort) the time from their first positive test to AIDS onset was much shorter than the time from seroconversion to AIDS onset.

Any reasonable predictions must be based on observing the distribution of AIDS incubation times in another cohort. Suppose that we obtain data from a study of homosexual men who underwent regular HIV-1 testing, and we then assemble from these data a study cohort of men who were observed to seroconvert. Suppose also that most of these men were followed for at least 5 years after seroconversion. We cannot expect any member of this study to be ‘just like’ any member of our target cohort in every respect. Nevertheless, if we could identify no differences between the two cohorts with respect to factors that affect incubation time, we might argue that the study cohort could serve as a point of reference for predicting incubation times in the target cohort. Thus, we shall henceforth refer to the study cohort as our reference cohort.

Note that our reference and target cohorts may have originated from different populations; for example, the clinic generating the target cohort could be in New York, but the study that generated the reference cohort may have been in San Francisco. Of course, for both the target and reference cohorts, the actual times of HIV-1 infection will have to be imputed, based on the dates of the last negative and the first positive tests.

Suppose that our statistical analysis of data from the reference cohort produces estimates of 0.05, 0.25, and 0.45 for the average risk of contracting AIDS within 2, 5, and 8 years of HIV-1 infection. What conditions would be sufficient to guarantee the validity of these figures as estimates or predictions of the proportion of the target cohort that would develop AIDS within 2, 5, and 8 years of infection? If by ‘valid’ we mean that any discrepancy between our predictions and the true target proportions is unbiased or purely random (unpredictable in principle), the following conditions would be sufficient:

- (C) *Comparison validity*—the distribution of incubation times in the target cohort will be approximately the same as the distribution in the reference cohort.
- (F) *Follow-up validity*—within the reference cohort, the risk of censoring (i.e. follow-up ended by an event other than AIDS) is not associated with risk of AIDS.
- (M) *Measurement validity*—all measurements of variables used in the analysis closely approximate the true values of the variables. In particular, each imputed time of HIV-1 infection closely approximates the true infection time, and each reported time of AIDS onset closely approximates a clinical event defined as AIDS onset.
- (Sp) *Specification validity*—the distribution of incubation times in the reference cohort can be closely approximated by the statistical model used to compute the estimates. For example, if one employs a lognormal distribution to model the distribution of incubation times in the reference cohort, this model should be approximately correct.

The first condition concerns the external validity of making predictions about the target cohort based on the reference cohort. The remaining conditions concern the internal validity of the predictions as estimates of average risk in the reference cohort. The following subsections will explore the meaning of these conditions in prediction problems.

Comparison validity

Comparison validity is probably the easiest condition to describe, although it is difficult to evaluate. Intuitively, it simply means that the distribution of incubation times in the target cohort could be almost perfectly predicted from the distribution of incubation times in the reference cohort, if the incubation times were observed without error and there was no loss to follow-up. Other ways of stating this condition are that the two cohorts are comparable or exchangeable with respect to incubation times, or that the AIDS experience of the target cohort can be predicted from the experience of the reference cohort.

Confounding

If the two cohorts are not comparable, some or all of our risk estimates for the target cohort based on the reference cohort will be

biased as a result. This bias is sometimes called *confounding*. There has been much research on methods for identifying and adjusting for such bias; see the textbooks cited earlier.

To evaluate comparison validity, we must investigate whether the two cohorts differ on any factors that influence incubation time. If so, we cannot reasonably expect the incubation time distributions of the two cohorts to be comparable. A factor responsible for some or all of the confounding in an estimate is called a confounder or confounding variable, the estimate is said to be confounded by the factor, and the factor is said to confound the estimate.

To illustrate these concepts, suppose that men infected at younger ages tend to have longer incubation times and that the members of the reference cohort are on average younger than members of the target cohort. If there were no other differences to counterbalance this age difference, we should then expect that members of the reference cohort will on average have longer incubation times than members of the target cohort. Consequently, unadjusted predictions of risk for the target cohort derived from the reference cohort would be biased (confounded) by age in a downward direction. In other words, age would be a confounder for estimating risk in the target cohort, and confounding by age would result in underestimation of the proportion of men in the target cohort who will develop AIDS within 5 years.

Now suppose that we can compute the age at infection of men in the reference cohort, and that within 1-year strata of age, for instance, the target and reference cohorts had virtually identical distributions of incubation times. The age-specific estimates of risk derived from the reference cohort would then be free of age confounding and so could be used as unconfounded estimates of age-specific risk for men in the target cohort. Also, if we wished to construct unconfounded estimates of average risk in the entire target cohort, we could do so via the technique of age standardization.

To illustrate, let P_x denote our estimate of the average risk of AIDS within 5 years of infection among members of the reference cohort who become infected at age x . Let W_x denote the proportion of men in the target cohort who are infected at age x . Then the estimated average risk of AIDS within 5 years of infection, standardized to the target cohort’s age distribution, is simply the average of the age-specific reference estimates P_x weighted by the age distribution (at infection) of the target cohort; algebraically, this average is the sum of the products $W_x P_x$ over all ages and is denoted by $\sum_x W_x P_x$. Considered as an estimate of the overall proportion of the target cohort that will contract AIDS within 5 years of HIV-1 infection, the standardized proportion $\sum_x W_x P_x$ will be free of age confounding.

The preceding illustration brings forth an important and often overlooked point: when one employs standardization to adjust for potential biases, the choice of standard distribution should never be considered arbitrary. In fact, the standard distribution should always be taken from the target cohort or the population about which inferences will be made. If inferences are to be made about several different groups, it may be necessary to compute several different standardized estimates.

Methods for removing bias in estimates by taking account of variables responsible for some or all of the bias are known as adjustment or covariate control methods. Standardization is perhaps the oldest and simplest example of such a method; methods

based on multivariate models are more complex. See also Cole and Stuart (2010) for an alternative approach to such adjustment using weighting.

Unmeasured confounders

If all confounders were measured accurately, comparison validity could be achieved simply by adjusting for these confounders (although various technical problems might arise when attempting to do so). Nevertheless, in any non-randomized study, we would ordinarily be able to think of a number of possible confounders that had not been measured or had been measured only in a very poor fashion. In such cases, it may still be possible to predict the direction of uncontrolled confounding by examining the manner in which persons were selected into the target and reference cohorts from the population at large. If the cohorts are derived from populations with different distributions of predictors of the outcome, or the predictors themselves are associated with admission differentially across the cohorts, these predictors will become confounders in the analysis.

To illustrate this approach, suppose that HIV-1 infection via an intravenous route (e.g. through needle sharing) leads to shorter incubation times than HIV-1 infection through sexual activity. Suppose also that the reference cohort had excluded all or most intravenous drug users, whereas the target cohort was non-selective in this regard. Then incubation times in the target cohort will on average be shorter than times in the reference cohort owing to the presence of intravenously infected persons in the target cohort. Thus we should expect the results from the reference cohort to underestimate average risks of AIDS onset in the target cohort.

Random sampling and confounding

Suppose, for the moment, that our reference cohort had been formed by taking a random sample of the target cohort. Can predictions about the target made from such a random sample still be confounded? With the definition of confounding given here, the answer is yes. To see this, note for example that by chance alone men in our sample reference cohort could be younger on average than the total target; this age difference would in turn downwardly bias the unadjusted risk predictions if men had longer incubation times at younger ages.

Nevertheless, random sampling can help to ensure that the distribution of the reference cohort is not too far from the distribution of the target cohort. In essence, the probability of severe confounding can be made as small as necessary by increasing the sample size. Furthermore, if random sampling is used, any confounding left after adjustment will be accounted for by the standard errors of the estimates, provided that the correct statistical model is used to compute the estimates and standard errors. We shall examine the latter condition under the subsection on specification validity.

Follow-up validity

In any cohort study covering an extended period of risk, subjects will be followed for different lengths of time. Some subjects will be lost to follow-up before the study ends. Others will be removed from the study by an event that precludes AIDS onset, which in this setting is death before AIDS onset from fatal accidents, fatal

myocardial infarctions, and so on. Because subjects come under study at different times, those who are not lost to follow-up or who die before developing AIDS will still have had different lengths of follow-up when the study ends; traditionally, a subject still under follow-up at the end of study is said to have been 'withdrawn from study' at this time.

Suppose that we wish to estimate the average risk of AIDS onset within 5 years of infection. The data from a member of the reference cohort who is not observed to develop AIDS but is also not followed for the full 5 years from infection are said to be censored for the outcome of interest (AIDS within 5 years of infection). Consider, for example, a subject killed in a car crash 2 years after infection but before contracting AIDS: the incubation time of this subject was censored at 2 years of follow-up.

Follow-up validity means that over any span of follow-up time, risk of censoring is unassociated with risk of the outcome of interest. In our example, follow-up validity means that over any span of time following infection, risk of censoring (loss, withdrawal, or death before AIDS) is unassociated with risk of AIDS. All common methods for estimating risk from situations in which censoring occurs (e.g. person-years, life table, and Kaplan-Meier methods) are based on the assumption of follow-up validity. Given follow-up validity, we can expect that, at any time t after infection, the distribution of incubation times will be the same for subjects lost or withdrawn at t and for subjects whose follow-up continues beyond t .

Violations of follow-up validity can result in biased estimates of risk; such violations are referred to as follow-up bias or biased censoring. To illustrate, suppose that younger reference subjects tend to have longer incubation times (i.e. lower risks) and are lost to follow-up at a higher rate than older reference subjects. In other words, lower-risk subjects are lost at a higher rate than higher-risk subjects. Then, after enough time, the average risk of AIDS in the observed portion of the reference cohort will tend to be overestimated; that is, higher than the average risk occurring in the full reference cohort (as the latter includes both censored and uncensored subject experience).

The follow-up bias in the last illustration would not affect the age-specific estimates of risk (where age refers to age at infection). Consequently, the age bias in follow-up would not produce bias in age-standardized estimates of risk. More generally, if follow-up bias can be traced to a particular variable that is a predictor of both the outcome of interest and censoring, bias in the estimates can be removed by adjusting for that variable. Thus, some forms of follow-up bias can be dealt with in the same manner as confounding.

Measurement validity

An estimate from a study can be said to have measurement validity if it suffers from no bias due to errors in measuring the study variables. Unfortunately, there are sources of measurement error in nearly all epidemiological studies, and nearly all sources of measurement error will contribute to bias in estimates. Thus, evaluation of measurement validity primarily focuses on identifying sources of measurement error and attempting to deduce the direction and magnitude of bias produced by these sources.

To aid in the task of identifying sources of measurement error, it can be useful to classify such errors according to their source. Errors from specific sources can then be further classified

according to characteristics that are predictive of the direction of the bias they produce. One classification scheme divides errors into three major categories, according to their source:

1. *Procedural error*: arising from mistakes or defects in measurement procedures
2. *Proxy-variable error*: arising from using a 'proxy' variable as a substitute for an actual variable of interest
3. *Construct error*: arising from ambiguities in the definition of the variables.

Regardless of their source, errors can be divided into two basic types, differential and non-differential, according to whether the direction or magnitude of error depends on the true values of the study variables. Two different sources of error may be classified as dependent or independent, according to whether or not the direction or magnitude of the error from one source depends on the direction or magnitude of the error from the other source. Finally, errors in continuous measurements can be factored into systematic and random components. As described in the following subsections, these classifications have important implications for bias.

Procedural error

Procedural error is the most straightforward to imagine. It includes errors in recall when variables are measured through retrospective interview (e.g. mistakes in remembering all medications taken during pregnancy). It also includes coding errors, errors in calibration of instruments, and all other errors in which the target of measurement is well defined and the attempts at measurement are direct but the method of measurement is faulty. In our example, one target of measurement is HIV-1 antibody presence in blood. All available tests for antibody presence are subject to error (false negatives and false positives), and these errors can be considered to be procedural errors of measurement.

Proxy-variable error

Proxy-variable error is distinguished from procedural error in that use of proxies necessitates imputation and hence virtually guarantees that there will be measurement error. In our example, we must impute the time of HIV-1 infection. For instance, we might take as a proxy the infection time computed as 6 weeks before the midpoint between the last negative test and the first positive test for HIV-1 antibodies. Even if our HIV-1 tests are perfect, this measurement incorporates error if (as is certainly the case) time of infection does not always occur 6 weeks before the midpoint between the last negative and first positive tests.

Construct error

Construct error is often overlooked, although it may be a major source of error. Consider our example in which the ultimate target of measurement is the time between HIV-1 infection and onset of AIDS. Before attempting to measure this time span, we must unambiguously define the events that mark the beginning and end of the span. While it may be reasonable to think of HIV-1 infection as a point event, the same cannot be said of AIDS onset. Symptoms and signs may gradually accumulate, and then it is

only by convention that some point in time is declared the start of the disease. If this convention cannot be translated into reasonably precise clinical criteria for diagnosing the onset of AIDS, the construct of incubation time (the time span between infection and AIDS onset) will not be well defined let alone accurately measurable. In such situations, it may be left to various clinicians to improvise answers to the question of time of AIDS onset, and this will introduce another source of extraneous variation into the final 'measurement' of incubation time.

Differential and non-differential error

Errors in measuring a variable are said to be differential when the direction or magnitude of the errors tend to vary across the true values of other variables. Suppose, for example, that recall of drug use during pregnancy is enhanced among mothers of children with birth defects. Then, a retrospective interview about drug use during pregnancy will yield results with differential error, as false-negative error will occur more frequently among mothers whose children have no birth defects.

Another type of differential error occurs in the measurement of continuous variables when the distribution of errors varies with the true value of the variable. Suppose, for example, that women more accurately recall the date of a recent cervical-smear (Papanicolaou) test than the date of a more distant test. Then, a retrospective interview to determine length of time since a woman's last cervical smear test would tend to suffer from larger errors when measuring longer times.

Errors in measuring a variable are said to be non-differential with respect to another variable if the magnitudes of errors do not tend to vary with the true values of the other variable. Measurements are usually assumed to be non-differential if neither the subject nor the person taking the measurement knows the values of other variables. For example, if drug use during pregnancy is measured by examining pre-partum prescription records for the mother, it would ordinarily be assumed that the error will be non-differential with respect to birth defects discovered postnatally. Nevertheless, such 'blind' assessments will not guarantee non-differential error if the measurement scale is not as fine as the scale of the original variable (Flegal et al. 1999; Wacholder et al. 1991) or if there is a third uncontrolled variable that affects both the measurement and the other study variables.

Dependent and independent error

Errors in measuring two variables are said to be dependent if the direction or magnitude of the errors made in measuring one of the variables is associated with the direction or magnitude of the errors made in measuring the other variable, conditional on the true variables. If there is no such association of errors, the errors are said to be independent.

In our example, errors in measuring age at HIV-1 infection and AIDS incubation time are dependent. Our measure of incubation time is equal to our measure of age at AIDS onset minus our measure of age at infection; hence, overestimation of age at infection will contribute to underestimation of incubation time, and underestimation of age at infection will contribute to overestimation of incubation time. In contrast, in the same example, it is plausible that the errors in measuring age at infection and age at onset are independent.

Systematic and random components of error

For well-defined measurement procedures on continuous variables, measurement errors can be subdivided into systematic and random components. The systematic component (sometimes called the bias of the measurement) measures the degree to which the procedure tends to underestimate or overestimate the true value on repeated application. The random component is the residual error left after subtracting the systematic component from the total error.

To illustrate, suppose that in our study HIV-1 infection time was unrelated to time of antibody testing and that the average time of HIV-1 seroconversion was 8 weeks after infection. Then, even if one used a perfect HIV-1 test, a procedure that estimated infection time as 6 weeks before the midpoint between the last negative and first positive test would on average yield an estimated infection time that was 2 weeks later than the true time. Thus, the systematic component of the error of this procedure would be +2 weeks. Because AIDS incubation time is AIDS onset time minus HIV-1 infection time, use of this procedure would add -2 weeks (i.e. a 2-week underestimation) to the systematic component of error in estimating incubation time.

Each of the components of an error, systematic and random, may be differential (i.e. may vary with other variable values) or non-differential, and may or may not be independent of the error components in other variables. We shall not explore the consequences of the numerous possibilities. However, one important (but semantically confusing) fact is that, for certain quantities, independent and non-differential systematic components of error will not harm measurement validity in that they will produce no bias in estimation (Poole 1985).

To illustrate, suppose that in our example we wish to estimate the degree to which AIDS incubation time depends on age at HIV-1 infection. Suppose also that the systematic components of the measurements of incubation time and age of infection are -2 weeks and +2 weeks (as mentioned), and do not vary with true incubation time or age at measurement (i.e. the systematic components are non-differential). Then, the systematic components, being equal, will cancel out when we compute differences in incubation time and differences in age at infection. Because only these differences are used to estimate the association, the observed dependence of incubation time on age at infection will not be affected by the systematic components of error (although it may be biased by the random components of error).

Specification validity

All statistical techniques, including so-called 'distribution-free' or 'non-parametric' methods as well as basic contingency table methods, are derived by assuming the validity of a sampling model or error distribution. A common example is the binomial model, which is discussed in all the textbooks cited in the introduction. For parametric methods, the sampling model is a mathematical formula that expresses the probability of observing the various possible data patterns as a function of certain unknown constants (parameters). Although the parameters of this model may be unknown, the mathematical form of this model incorporates only known or purely random aspects of the data-generation process; unknown systematic aspects of this process (such as most

follow-up and selection biases) will not be accounted for by the model.

All parametric statistical techniques also assume a structural model, which is a mathematical formula that expresses the parameters of the sampling model as a function of study variables. A common example is the logistic model (Kelsey et al. 1996; Hosmer and Lemeshow 2000; Checkoway et al. 2004; Jewell 2004; Greenland 2008a, 2008b). The structural model is most often incorporated into the sampling model, and the combination is referred to as the statistical model. An estimate can be said to have specification validity if it is derived using a statistical model that is correct or nearly so.

If either the sampling model or the structural model used for analysis is incorrect, the resulting estimates may be biased. Such bias is sometimes called specification bias, and the use of an incorrect model is known as model misspecification or specification error. Even when misspecification does not lead to bias, it can lead to invalidity of statistical tests and confidence intervals.

The true structural relation among the study variables is almost never known in studies of human disease. Furthermore, in the absence of random sampling and randomization, the true sampling process (i.e. the exact process leading people to enter and stay in the study groups) will also be unknown. It follows that we should ordinarily expect some degree of specification error in an epidemiological analysis. Minimizing such error largely consists of contrasting the statistical model against the data and against any available information about the processes that generated the data, such as prior information on demographic patterns of incidence.

Many statistical techniques in epidemiology are based on assuming some type of logistic model. Examples include all the popular adjusted odds ratios, such as the Woolf, ML, and Mantel-Haenszel estimates, as well as tests for odds ratio heterogeneity. Classical 'indirect' adjustment of rates and other comparisons of standardized morbidity ratios depend on similar multiplicative models for their validity (Breslow and Day 1987).

The degree of bias in traditional epidemiological analysis methods when the model assumptions fail has not been extensively studied. A few traditional methods, such as directly standardized comparisons and the Mantel-Haenszel test, remain valid under a wide variety of structural models. In addition, risk regression has been extended to situations involving more general models than assumed in classical theory (Breslow and Day 1987; Hastie and Tibshirani 1990). Leamer (1978) and White (1993) give more details on the effects of specification error in multiple regression problems, and Maldonado and Greenland (1994) and Greenland and Maldonado (1994) examine the implications of specification error in epidemiology.

Summary of prediction example

The example in this subsection provides an illustration of the most common threats to the validity of predictions. The unadjusted estimates of AIDS risk may be confounded if the target and reference cohorts differ in composition, and may also be biased by losses to follow-up or use of an incorrect statistical model. Finally, our predictions are likely to be compromised by errors in measurements. These sources of error should be borne in mind in any attempt to predict AIDS incidence.

Validity and bias in causal inference

All the bias problems in prediction arise in studies of causation; confounding, follow-up bias, measurement errors, and specification errors must be considered. In fact, as we shall see, problems of causal inference can be viewed as a special type of prediction problem, namely prediction of what would happen (or what would have happened) to a population if certain characteristics of the population were (or had been) altered (Greenland, 2012b).

To illustrate the validity issues in causal inference, we shall consider the hypothesis that coffee drinking causes acute myocardial infarction. This hypothesis can be operationally interpreted in a number of ways, such as

1. There are people for whom the consumption of coffee results in their experiencing a myocardial infarction sooner than they might have, had they avoided coffee.

Although this hypothesis is appealingly precise, it offers little practical guidance to an epidemiological researcher. The problem lies in our inability to recognize an individual whose myocardial infarction was caused by coffee drinking. It is quite possible that myocardial infarctions precipitated by coffee use are clinically and pathologically indistinguishable from myocardial infarctions due to other causes. If so, the prospect of testing this hypothesis with purely physiological evidence is not good.

We could overcome this impasse by examining a related epidemiological hypothesis; that is, a hypothesis that refers to the distribution of disease in populations. One of many such hypotheses is

2. Among five-cup-a-day coffee drinkers, cessation of coffee use will lower the frequency of myocardial infarction.

This form not only involves a population (five-cup-a-day coffee drinkers) but also asserts that a mass action (coffee cessation) will reduce the frequency of the study disease. Thus, the form of the hypothesis immediately suggests a strong test of the hypothesis: conduct a randomized intervention trial to examine the impact of coffee cessation on myocardial infarction frequency. This solution has some profound practical limitations, not least of which would be persuading anyone to give up or take up coffee drinking to test a speculative hypothesis.

Having ruled out intervention, we might consider an observational cohort study. In this case, our epidemiological hypothesis must refer to natural conditions, rather than intervention. One such hypothesis is

3. Among five-cup-a-day coffee drinkers, coffee use has elevated the frequency of myocardial infarction.

There have been many conflicting cohort and case-control studies of coffee and myocardial infarction. The present discussion will be confined to the issues arising in the analysis of a single study. For a review of issues arising in the analysis of multiple studies (meta-analysis) see Greenland (1994) and Greenland and O'Rourke (2008).

Consider a cohort study of coffee and first myocardial infarction. At baseline, a cohort of people with no history of myocardial infarction is assembled and classified into subcohorts according to coffee use (e.g. never-drinkers, ex-drinkers, occasional drinkers, one-cup-a-day drinkers, two-cup-a-day drinkers, etc.). Other variables are measured as well: age, gender, smoking habits, blood pressure, and serum cholesterol. Suppose that at the end of 10 years of monitoring this cohort for myocardial infarction

events, we compare the five-cup-a-day and never-drinker subcohorts, and obtain an unadjusted estimate of 1.22 for the ratio of the person-time incidence rates of first myocardial infarction among five-cup-a-day drinkers and never-drinkers (with 95 per cent CIs of 1.00 and 1.49). In other words, it appears that the rate of first myocardial infarction among five-cup-a-day drinkers was 1.22 times higher than the rate among never-drinkers. (Hereafter, myocardial infarction means first myocardial infarction, risk means average risk, and rate means person-time incidence rate.)

The estimated rate ratio of 1.22 may not seem large. Nevertheless, if it accurately reflects the impact of coffee use on the five-cup-a-day subcohort, this estimate implies that persons drinking five cups a day at baseline suffered a 22 per cent increase in their myocardial infarction rate as a result of their coffee use. Given the high frequency of both coffee use and myocardial infarction in many populations, this could represent a substantial health impact. Therefore, we would want to perform a careful evaluation of possible bias in the estimate.

As in the AIDS example, we can proceed by examining a series of conditions sufficient for validity of the estimate as a measure of the effect of coffee:

- (C) *Comparison validity (no confounding)*—if the members of the five-cup-a-day subcohort had instead never drunk coffee, their distribution of myocardial infarction events over time would have been approximately the same as the distribution among the never-drinkers.
- (F) *Follow-up validity*—within each subcohort, the risk of censoring (i.e. follow-up ended by an event other than myocardial infarction) is not associated with the risk of myocardial infarction.
- (M) *Measurement validity*—all measurements of variables used in the analysis closely approximate the true values of the variables.
- (Sp) *Specification validity*—the distribution of myocardial infarction events over time in the subcohorts can be closely approximated by the statistical model on which the estimates are based.

These four conditions are sometimes called *internal validity conditions* because they pertain only to estimating effects within the study cohort rather than to generalizing results to other cohorts. They are sufficient but not necessary for validity, in that certain violations of the conditions will not produce bias in the effect estimate (although most violations will produce some bias).

The meaning of these conditions for an observational cohort study of a causal hypothesis is explored in the following subsections. An important phenomenon known as *effect modification*, which is relevant to both internal validity and generalizability, will also be discussed following comparison validity.

Comparison validity

In our example, comparison validity means that the distribution of myocardial infarctions among never-drinkers accurately predicts what would have happened in the coffee-drinking groups had the members of these groups never drunk coffee. Another way of stating condition C is that the five-cup-a-day and never-drinker subcohorts would be comparable or exchangeable with respect to myocardial infarction times if no one had ever drunk coffee, or

that there is no confounding (Greenland et al. 1991; Rothman et al. 2008, chapter 4).

Despite its simplicity, comparison validity depends on the hypothesis of interest in a very precise way. In particular, the research hypothesis (hypothesis 3 in the preceding subsection) is a statement about the impact of coffee among five-cup-a-day drinkers. Thus, this subcohort is the target cohort, and never-drinkers serve as the reference cohort for making predictions about this target.

To illustrate further the correspondence between comparison validity and the hypothesis at issue, suppose for the moment that our research hypothesis was:

4. Among never-drinkers, five-cup-a-day coffee use would elevate the frequency of myocardial infarction.

In examining this hypothesis, the never-drinkers would be the target cohort and the coffee drinkers would be the reference cohort. Thus, the comparison validity condition would have to be replaced by a condition such as

- (C') If the never-drinkers had drunk five cups of coffee per day, their distribution of myocardial infarctions would have been approximately the same as the distribution among five-cup-a-day drinkers.

Other ways of stating condition C' are that the five-cup-a-day and never-drinker subcohorts would be comparable or exchangeable with respect to time to myocardial infarction if everyone had been five-cup-a-day drinkers, and that the myocardial infarction experience of five-cup-a-day drinkers accurately predicts what would have happened to the never-drinkers if the latter had drunk five cups a day.

Confounding

Failure to meet condition C results in a biased estimate of the effect of five-cup-a-day coffee drinking on five-cup-a-day drinkers, a condition sometimes referred to as confounding of the estimate. Similarly, failure to meet condition C' results in a biased estimate of the effect that five-cup-a-day drinking would have had on never-drinkers.

To evaluate potential confounding, we must check whether the subcohorts differed at baseline on any factors that influence time to myocardial infarction. If so, we could not reasonably expect the myocardial infarction distributions of the subcohorts to be comparable, even if the subcohorts had the same level of coffee use. In other words, we could not expect condition C (or C') to hold, and so we should expect our estimates to suffer from confounding. This is so, regardless of whether adjustment appears to change the association of coffee use and myocardial infarction (Greenland et al. 1999).

Some studies have found a positive association between cigarette smoking (an established risk factor for myocardial infarction) and coffee use (Greenland 1993). It also seems a priori sensible that a person habituated to a stimulant such as nicotine would be attracted to coffee use as well. Thus, we should expect to see a higher prevalence of smoking among coffee users in our study.

Suppose then that, in our cohort, smoking is more prevalent among five-cup-a-day subjects than never-drinkers. This elevated smoking prevalence should have led to elevated myocardial infarction rates among five-cup-a-day drinkers, even if coffee had

no effect. More generally, we should expect the myocardial infarction rate among never-drinkers to underestimate the myocardial infarction rate that five-cup-a-day drinkers would have had if they had never drunk coffee. The result would be an inflated estimate of the impact of coffee on the myocardial infarction rate of five-cup-a-day drinkers. Similarly, we should expect the myocardial infarction rate among five-cup-a-day drinkers to overestimate the myocardial infarction rate that never-drinkers would have had if they had drunk five cups a day.

Adjustment for measured confounders

As in the prediction problem, we can stratify the data on potential confounders with the objective of creating strata within which confounding is minimal or absent. We can also employ standardization to remove confounding from estimates of overall effect. Again, some care in the selection of the standard is required.

To illustrate, let R_{xz} denote the estimated rate of myocardial infarction among cohort members who drank x cups of coffee per day and smoked z cigarettes per day at baseline, with R_{0z} denoting the estimated rate among never-drinkers. Let W_{xz} denote the proportion of person-time among x -cup-per-day drinkers that was contributed by z -cigarette-per-day smokers. Finally, let R_{xc} be the unadjusted rate observed among cohort members who drank x cups per day at baseline, with R_{0c} denoting the estimated unadjusted rate among never-drinkers.

Suppose for the moment that any change in coffee-use patterns would have negligible impact on the person-time distribution of smoking in the cohort. The predicted (i.e. expected) rate among five-cup-a-day drinkers had they never drunk coffee, adjusted for confounding by smoking, is the average of the smoking-specific estimates from the never-drinker (reference) subcohort weighted by the smoking distribution of the five-cup-per-day (target) cohort. Algebraically, this average is the following sum (over z):

$$\sum_z W_{sz} R_{0z}.$$

This sum is commonly termed the rate in the never-drinkers standardized to the distribution of smoking among five-cup-a-day drinkers. Such terminology obscures the fact that the sum is a prediction about the five-cup-a-day drinkers, not the never-drinkers.

Given the last computation, a smoking-standardized estimate of the increase in myocardial infarction rate produced by coffee drinking among five-cup-per-day drinkers is the rate ratio standardized to the five-cup-per-day smoking distribution:

$$\sum_z W_{sz} R_{sz} / \sum_z W_{sz} R_{0z}.$$

This formula reveals a property common to a simple standardized rate ratio: The same weights W_{xz} must be used in the numerator and denominator sums. Some insight into this formula can be obtained by noting that the unadjusted rate R_{5c} , among the five-cup-a-day drinkers, is equal to:

$$\sum_z W_{sz} R_{sz},$$

so that the standardized rate ratio can be rewritten as:

$$R_{5c} / \sum_z W_{sz} R_{0z}.$$

This version shows that the ratio is a classical observed unadjusted rate over the rate expected without exposure, or standardized morbidity ratio (SMR). Another standardized rate ratio is:

$$\sum_z W_{0z} R_{sz} / \sum_z W_{0z} R_{0z}.$$

This differs from the previous standardized ratio in that the weights are taken from the never-drinkers (W_{0z}) instead of five-cup-a-day drinkers (W_{5z}). Insight into this formula can be obtained by noting that the numerator sum is simply a prediction (expectation) of what would have happened to the never-drinkers if they had been five-cup-a-day drinkers, and the denominator sum is equal to the unadjusted rate $R_{0\cdot}$ among never-drinkers. Thus, the last standardized ratio is a smoking-standardized estimate of the increase in the myocardial infarction rate that five-cup-a-day drinking would have produced among the never-drinkers.

Standardization is appealingly simple in both justification and computation. Unfortunately, if the number of cases occurring within the confounder categories tends to be small (under five or so), the technique will be subject to various technical problems including possible bias. These problems can be avoided by broadening confounder categories or by not adjusting for some of the measured confounders. Unfortunately, both these strategies are likely to result in incomplete control of confounding. To avoid having to adopt these strategies, many researchers attempt to control confounding by using a multivariate model. This remedy has problems of its own, some of which we shall address in the subsection on specification validity.

Another problem is that standardized procedures (as well as typical modelling procedures) take no account of potential exposure effects on the adjustment variables or their distribution. Thus, in the preceding example, to justify use of the fixed weights W_{xz} we had to invoke the dubious assumption that changes in coffee use would only negligibly affect the smoking distribution. We shall briefly discuss this issue in the subsection on intermediate variables.

Unmeasured confounders

Among the possible confounders not measured in our hypothetical study are diet and exercise. Suppose that 'health conscious' subjects who exercise regularly and eat low-fat diets also avoid coffee. The result will be a concentration of these lower-risk subjects among coffee non-users and a consequent overestimation of coffee's effect on risk.

Confounding by unmeasured confounders can sometimes be minimized by controlling variables along the pathways of their effect. For example, if exercise and a low-fat diet lowered myocardial infarction risk only by lowering serum cholesterol and blood pressure, control of serum cholesterol and blood pressure would remove confounding by exercise and dietary fat. Unfortunately, such control may also generate bias if the controlled variables are intermediates between our study variable and our outcome variable.

If external information is available to indicate the relationship in our study between an unmeasured confounder and the study variables, we can attempt to use an indirect method to adjust for the confounder; even if external information is unreliable or unavailable, we can examine the sensitivity of our results to unmeasured confounders (Greenland and Lash 2008;

VanderWeele and Arah 2011). Sometimes we can also predict the direction of the bias resulting from confounding (VanderWeele 2008; VanderWeele et al. 2008). Finally, we can evaluate the impact that uncertainty about unmeasured confounders should have on our final inferences about the effect (Greenland and Lash 2008; Lash et al. 2009).

Randomization and confounding

Suppose, for the moment, that the level of coffee use in our cohort had been assigned by randomization and that the participants diligently consumed only their assigned amount of coffee. Could our estimates of coffee effects from such a randomized trial still be confounded? By our earlier definition of confounding, the answer is yes. To see this, note for example that by chance alone the five-cup-a-day drinkers could be older on average than the never-drinkers; this difference would in turn result in an upward bias in the unadjusted estimate of the effect of five cups a day, because age is an important risk factor for myocardial infarction.

Nevertheless, randomization can help to ensure that the distributions of confounders in the different exposure groups are not too far apart. In essence, the probability of severe confounding can be made as small as necessary by increasing the size of the randomized groups. Furthermore, if randomization is used and subjects comply with their assigned treatments, any confounding left after adjustment will be accounted for by the standard errors of the estimates, provided that the correct statistical model is used to compute the effect estimates and their standard errors (Robins 1988; Greenland 1990).

Intermediate variables

In effect estimation, we must take care to distinguish intermediate variables from confounding variables. Intermediate variables represent steps in the causal pathway from the study exposure to the outcome event. The distinction is essential, for control of intermediate variables can increase the bias of estimates.

To illustrate, suppose that coffee use affects serum cholesterol levels (as suggested by the results of Curb et al. (1986)). Then, given that serum cholesterol affects myocardial infarction risk, serum cholesterol is an intermediate variable for the study of the effects of coffee on this risk. Now suppose that we stratify our cohort data on serum cholesterol levels. Some coffee drinkers will be in elevated cholesterol categories because of coffee use and so will have an elevated risk of myocardial infarction, yet these subjects will be compared with never-drinkers in the same stratum who are also at elevated risk due to their elevated cholesterol. Therefore, the effect of coffee on the risk of myocardial infarction via the cholesterol pathway will not be apparent within the cholesterol strata, and so cholesterol adjustment will contribute to underestimation of the effect of coffee on risk of myocardial infarction. Analogously, if coffee affected the risk of myocardial infarction by elevating blood pressure, blood pressure adjustment will contribute to underestimation of the effect of coffee. Such underestimation can be termed overadjustment bias.

Intermediate variables may also be confounders and thus present the investigator with a severe dilemma. Consider that most of the variation in serum cholesterol levels is not due to coffee use and that much (perhaps most) of the association between coffee use and cholesterol is not due to the effects of coffee, but rather to

factors associated with both coffee and cholesterol (such as exercise and dietary fat). This means that serum cholesterol may also be viewed as a confounder for the coffee–myocardial infarction study and that estimates unadjusted for serum cholesterol will be biased unless they are also adjusted for the factors contributing to the coffee–cholesterol association.

Suppose that a variable is both an intermediate and a confounder. It will usually be impossible to determine how much of the change in the effect estimate produced by adjusting for the variable is due to introduction of overadjustment bias and how much is due to removal of confounding. Nevertheless, a qualitative assessment may be possible in some situations. For example, if we know that the effects of coffee on serum cholesterol are weak and that most of the association between coffee and serum cholesterol is due to confounding of this association by uncontrolled factors (such as exercise and diet), we can conclude that the cholesterol-adjusted estimate is probably the less biased of the two. Alternatively, if we have accurately measured all the factors that confound the coffee–cholesterol association, we can control these factors instead of cholesterol to obtain an estimate free of both overadjustment bias and confounding by cholesterol. Finally, if we have multiple measurements of coffee use and cholesterol over time, techniques are available that adjust for the confounding effects of cholesterol but do not introduce overadjustment (Hernán et al. 2000; Robins et al. 2000).

Direct and indirect effects

Often, one may wish to estimate how much of the effect under study is indirect relative to an intermediate variable (in the sense of being transmitted through the intermediate), or how much of the effect is direct relative to the intermediate (i.e. not mediated by the intermediate). For example, we might wish to estimate how much of the effect of coffee on myocardial infarction risk is due to its effect on serum cholesterol, or how much is due to the effects of coffee on cardiovascular variables other than cholesterol.

One common approach to this problem is to adjust the coffee–myocardial infarction association for serum cholesterol level via ordinary stratification or regression methods and then use the resulting estimate as the estimate of the direct effect of coffee. This procedure is potentially biased as it may introduce new confounding by determinants of serum cholesterol, even if these determinants did not confound the total (unadjusted) association (Robins and Greenland 1992, 1994; Cole and Hermán 2002; Glymour and Greenland 2008). Nonetheless, given sufficient data, it is possible to obtain separate estimates for direct and indirect effects using special stratification or modelling techniques (Robins and Greenland 1994; Kaufman et al. 2005; Vansteelandt 2010, 2012; Valeri and VanderWeele et al. 2013), but again these techniques make much stronger assumptions than those for total effects. These assumptions can be assessed to a certain extent using sensitivity analysis (VanderWeele 2010).

Effect modification (heterogeneity of effect)

Estimation of effects usually requires consideration of effect-measure modification, which is also known as effect modification, effect variation, or heterogeneity of effect. As an example, suppose that drinking five cups of coffee a day elevated the myocardial infarction rate of men in our cohort by a factor of 1.40 (i.e. a 40 per cent increase), but elevated the myocardial infarction rate

of women by a factor of only 1.10 (i.e. a 10 per cent increase). This situation would be termed modification (or variation or heterogeneity) of the rate ratio by gender, and gender would be called a modifier of the coffee–myocardial infarction rate ratio.

As another example, suppose that drinking five cups of coffee a day elevated the myocardial infarction rate in men in our cohort by a factor of 400 cases per 100,000 person-years but elevated the rate in women by a factor of only 40 cases per 100,000 person-years. This situation would be termed modification of the rate difference by gender, and gender would be called a modifier of the coffee–myocardial infarction rate difference.

As a final example, suppose that drinking five cups of coffee per day elevated the myocardial infarction rate in our cohort by a factor of 1.22 in both men and women. This situation would be termed homogeneity of the rate ratios across gender.

Effect modification and homogeneity are not absolute properties of an effect, but instead are properties of the way that the effect is measured. For example, suppose that drinking five cups of coffee per day elevated the myocardial infarction rate in men from 1000 cases per 100,000 person-years to 1220 cases per 100,000 person-years, but elevated the rate in women from 400 cases per 100,000 person-years to 488 cases per 100,000 person-years. Then the gender-specific rate ratios would both be 1.22, homogeneous across gender. In contrast, the gender-specific rate differences would be 220 cases per 100,000 person-years for males and 88 cases per 100,000 person-years for females, and so are heterogeneous or ‘modified’ by gender. Examples such as this one show that one should not equate effect modification with biological concepts of interaction such as synergy or antagonism (Greenland and O’Rourke 2008; VanderWeele 2009).

Effect modification can be analysed by stratifying the data on the potential effect modifier under study, estimating the effect within each stratum, and comparing the estimates across strata. There are several potential problems with this approach. The number of subjects in each stratum may be too small to produce stable estimates of stratum-specific effects, particularly after adjustment for confounder effects. Estimates may fluctuate wildly from stratum to stratum owing to random error. A related problem is that statistical tests for heterogeneity in stratified data have extremely low power in many situations, and therefore are likely to miss much if not most of the heterogeneity when used with conventional significance levels (such as 0.05). Finally, the amount of bias from confounding, loss to follow-up, measurement error, and other sources may vary from stratum to stratum, in which case the observed pattern of modification will be biased.

Effect modification and generalizability

Suppose that we succeed in obtaining approximately unbiased (internally valid) estimates from our study. We can then confront the issues of generalizability (external validity) of our results. For example, we can ask whether they accurately reflect the effect of coffee on myocardial infarction rates in a new target cohort. We can view such a question as a prediction problem in which the objective is to predict the strength of the effects of coffee in the new target cohort. From this perspective, generalizability of an effect estimate involves just one additional validity issue, namely confounding of the predicted effect by effect modifiers.

Suppose that the rate increase (in cases per 100,000 person-years) produced by coffee use is 400 for males and 40 for females among

five-cup-a-day drinkers in both our study cohort and the new target. If our study cohort is 70 per cent male, while the new target is only 30 per cent male, the average increase among five-cup-a-day drinkers in our study cohort would be $0.7 \times 400 + 0.3 \times 40 = 292$, whereas the average increase in the new target would be only $0.3 \times 400 + 0.7 \times 40 = 148$. Thus, any valid estimate of the average increase in our study cohort will tend to overestimate greatly the average increase in the new target. In other words, modification of the effect of coffee by gender confounds the prediction of its effect in the new target. This bias can be avoided by making only gender-specific predictions of effect or by standardizing the study results to the gender distribution of the new target population.

Follow-up validity

In our example, follow-up validity means that follow-up is valid within every subcohort being compared. In other words, over any span of time during follow-up, risk of myocardial infarction within a subcohort is unassociated with censoring risk in the subcohort. Given follow-up validity, we can expect that, at any follow-up time t , the myocardial infarction rates in a subcohort will be the same for subjects lost or withdrawn at t and subjects whose follow-up continues beyond t .

In fact, we should expect follow-up to be biased by cigarette smoking: smoking is associated with mortality from myocardial infarction and from many other causes; the association of smoking with socioeconomic status might also produce an association between smoking and loss to follow-up. The result would be elevated censoring among high-risk (smoking) subjects. As a consequence, unadjusted estimates of the risks of myocardial infarction will underestimate those risks in the complete subcohorts (as the latter includes both censored and uncensored subject experience). If the degree of underestimation varies across subcohorts, bias in the relative-risk estimates will result.

In fact, the degree of underestimation should vary in this example because of the variation in the prevalence of smoking across subcohorts. Nevertheless, this variation is not necessary for smoking-related censoring to produce biased estimates of absolute effect. For example, if smoking-related censoring produced a uniform 15 per cent underestimation of the myocardial infarction rate in each subcohort, all rate differences would also be underestimated by 15 per cent.

Analogous to control of confounding, any bias produced by the association of smoking with myocardial infarction and censoring can be removed by smoking adjustment. As before, if adjustment is by standardization, the standard distribution should be chosen from the target subcohort.

Because the same correction methods can sometimes be applied, some authors classify follow-up bias as a form of confounding. Nevertheless, the two phenomena are reversed with respect to the causal ordering of the third variable responsible for the bias: confounding arises from an association of the study exposure (coffee use) with other exposures (such as smoking) that affect outcome risk; in contrast, follow-up bias arises from an association between the risk of the study outcome (myocardial infarction) and risks of other end points (such as other-cause mortality or loss to follow-up) that are affected by exposure, and thus is classified as a form of selection bias by many authors (Kelsey et al. 1996; Hernán et al. 2004). In this regard, note that certain forms of follow-up bias cannot be removed by adjustment, and

thus do not resemble confounding (Hernán et al. 2004; Glymour and Greenland 2008). These problems are discussed in the statistics literature under the topic of dependent competing risks (Slud and Byar 1988) and resemble the selection-bias problems of case-control studies, which are discussed later.

Measurement validity

Unlike gender, the continuous variables of coffee use, cigarette use, blood pressure, cholesterol, and age are time-dependent covariates. With the exception of age (whose value at any time can be computed from birth date), this fact adds considerable complexity to measuring these variables and estimating their effects.

Consider that we cannot reasonably expect a single baseline measurement, no matter how accurate, to summarize adequately a subject's entire history of coffee drinking, smoking, blood pressure, or cholesterol. Even if the effect of a subject's history could be largely captured by using a single summary number (e.g. total number of cigarettes smoked), the baseline measurement may well be a poor proxy for this ideal and unknown summary. For these reasons, we should expect proxy-variable errors to be very large in our example.

Proxy-variable error in the study variables

The degree of proxy-variable error in measuring the study variables depends on the exact definitions of the variables that we wish to study. In turn, this definition should reflect the hypothesized effect that we wish to study. To illustrate, consider the following acute-effect hypothesis:

Drinking a cup of coffee produces an immediate rise in short-term myocardial infarction risk. In other words, coffee consumption is an acute risk factor.

This hypothesis does not exclude the possibility that coffee use also elevates long-term risk of myocardial infarction, perhaps through some other mechanism; it simply does not address the issue of chronic effects.

One way to examine the hypothesis would be to compare the myocardial infarction rates among person-days in which one, two, three, or more cups were drunk with the rate among person-days in which no coffee was drunk (adjusting for confounding and follow-up bias). If we had only baseline data, baseline daily consumption would have to serve as the proxy for consumption on every day of follow-up. This would probably be a poor proxy for daily consumption at later follow-up times where more outcome events occur. A 'standard' analysis, which only examines the association of baseline coffee use with myocardial infarction rates, is equivalent to an analysis that uses baseline consumption as a proxy for consumption on all later days. Thus, estimates from a standard analysis would suffer large bias if considered as estimates of the acute effects of coffee.

The proxy-variable error in this example could easily be differential with respect to the outcome: person-days accumulate more rapidly in early follow-up, where the error from using baseline consumption as the proxy is relatively low; in contrast, myocardial infarction events accumulate more rapidly in later follow-up, where the error is probably higher. This difference in accumulation illustrates an important general point: errors in variables can be differential, even if the variables are measured before the outcome event. Such phenomena occur when errors are associated with risk

factors for the outcome; in our example, the error is associated with follow-up time and hence age. In turn, such associations are likely to occur when measurements are based on proxy variables.

Suppose now that we examine the following chronic-effect hypothesis:

Each cup of coffee drunk eventually results in a long-term elevation of myocardial infarction risk.

This hypothesis was suggested by reports that coffee drinking produces a rise in serum lipid levels (Curb et al. 1986); it does not address the issue of acute effects. One way to examine the hypothesis would be to compare the myocardial infarction rates among person-months with different cumulative doses of coffee (perhaps using a lag period in calculating dose; e.g. one might ignore the most recent month of consumption). If we had only baseline data, however, baseline daily consumption would have to be used to construct a proxy for cumulative consumption at every month of follow-up. This construction could be done in several different ways. For example, we could estimate the subjects' cumulative doses up to a particular date by multiplying their baseline daily consumption by the number of days that they had lived between age 18 and the date in question. This estimate assumes that coffee drinking began at age 18 and the baseline daily consumption is the average daily consumption since that age. We should expect considerable error in such a crude measure of cumulative consumption.

The degree of bias in estimating chronic effects could be quite different from the degree of bias in estimating acute effects. Furthermore, as discussed in the following, the errors in each proxy will make it virtually impossible to discriminate between acute and chronic effects.

Misclassification and bias towards the null

Although measurement errors can bias effect estimates, in some cases one may be able to predict the direction of the bias. Measurement of a binary (dichotomous) variable is called better than random if, regardless of the true value, the probability that the measurement yields the true value is higher than the probability that it does not. In other words, the measurement is better than random if it is more likely to be correct than incorrect, no matter what the true value is. Given two binary variables, better-than-random measurements with independent non-differential errors cannot inflate or reverse the association observed between the variables. In other words, any bias produced by independent non-differential error in better-than-random measurements can only be towards the null value of the association (which is one for a relative-risk measure) and not beyond.

If either variable has more than two levels, then (contrary to assertions in most pre-1990 literature) the preceding conditions are not sufficient to guarantee that the resulting bias will only be towards the null and not beyond (Dosemeci et al. 1990). Despite this insufficiency, knowing that errors are independent and non-differential can increase the plausibility that any resulting bias is towards the null, although it should not increase the plausibility that the observed association is in the correct direction (Weinberg et al. 1994). For further discussions of measurement error and bias towards the null, see Flegal et al. (1991), Wacholder et al. (1991), Weinberg et al. (1994), Rothman et al.

(2008, chapter 9), VanderWeele and Hernán (2012), and Gustafson and Greenland (in press).

There is one important situation in which the assumption of independent non-differential measurement error and hence bias towards the null have particularly high plausibility: in a double-blind clinical trial with a dichotomous treatment and outcome, successful blinding of treatment status during outcome evaluation should lead to independence and non-differentiality of treatment and outcome measurement errors. Successful blinding thus helps to ensure (although it does not guarantee) that any bias produced by measurement error contributes to underestimation of treatment differences (conservative bias).

Measurement error and confounding

If a variable is measured with error, estimates adjusted for the variable as measured will still be somewhat confounded by the variable. This residual confounding arises because measurement error prevents construction of strata that are internally homogeneous with respect to the true confounding variable (Greenland 1980).

To illustrate, consider baseline daily cigarette consumption. This variable can be considered a proxy for consumption on each day of follow-up or can be used to construct an estimate of cumulative consumption (analogous to the cumulative coffee variable discussed in the preceding). Suppose that we stratify the data on a cumulative smoking index constructed from the baseline smoking measurement. Within any stratum of the index, there would remain a broad range of cumulative cigarette consumption. For example, two subjects who were age 40 and smoked one pack a day at baseline would receive the same value for the smoking index and so end up in the same stratum. However, if one of them stopped smoking immediately after baseline, while the other continued to smoke a pack a day, after 10 years of follow-up the former subject would have ten fewer pack-years of cigarette consumption than the continuing smoker.

Suppose now that cumulative cigarette consumption is positively associated with cumulative coffee consumption. Then, even within strata of the smoking index, we should expect subjects with high coffee consumption to exhibit elevated myocardial infarction rates simply by virtue of having higher levels of cigarette consumption. As a consequence, the estimate of the effect of coffee adjusted for the smoking index would still be confounded by cumulative cigarette consumption.

In some cases, a study variable may appear to have an effect (or no effect) only because of poor measurement of an apparently unimportant confounder. This can occur, for example, when an important confounding variable is measured with a large amount of non-differential error. Such an error would ordinarily reduce the apparent association of the variable with the exposure, and would also make the variable appear to be a weak risk factor, perhaps weaker than the study exposure. This in turn would make the variable appear to be only weakly confounding, in that adjustment for the variable as measured would produce little change in the result. However, this appearance would be deceptive because adjustment for the variable as measured would eliminate little of the actual confounding by the variable.

As an example, suppose that coronary proneness of personality was measured only by the baseline yes or no question: Do you consider yourself a hard-driving person? Such a crude measure of the original construct would be unlikely to show more than a

weak association with either coffee use or myocardial infarction, and adjusting for it would produce little change in our estimate of the effect of coffee. Suppose, however, that coronary-prone personalities have an elevated preference for coffee. Such a phenomenon would lead to a concentration of coronary-prone persons (and hence, a spuriously elevated myocardial infarction rate) among coffee drinkers, even after stratification on the response to the question.

One would ordinarily expect adjustment for a non-differentially misclassified confounder to produce an estimate lying somewhere between the unadjusted estimate and the estimate adjusted for the true values of the confounder (Greenland 1980). Unfortunately, if the true confounder has more than two levels, it is possible for adjustment by the misclassified confounder to be more biased than the unadjusted estimate (Brenner 1993); this can even happen with confounders with two levels if the confounder affects the exposed and unexposed subjects in opposite directions (Ogburn and VanderWeele 2012). It is also possible for adjustment by factors that affect misclassification to worsen bias (Greenland and Robins 1985). If however the effect of the confounder is in the same direction regardless of exposure, and its misclassification is independent and non-differential with respect to the exposure and outcome, adjustment for the misclassified confounder will on average produce an estimate between the unadjusted estimate and the estimate adjusted for the true confounder values (Ogburn and VanderWeele 2012, 2013).

Measurement error and separation of effects

Because of their impact on the effectiveness of adjustment procedures, measurement errors can severely reduce our ability to separate different effects of the study variable. Suppose in our example that we wished to estimate the relative strength of acute and chronic effects of coffee. To do so, we must take account of the fact that acute and chronic effects will be confounded. When examining acute effects, person-days with high coffee consumption will occur most frequently among persons with high cumulative coffee consumption. As a consequence, if cumulative coffee consumption is a risk factor, it will be a confounder for estimating the acute effects of coffee consumption. By similar arguments, if coffee consumption has acute effects, these will confound estimates of the chronic effects of cumulative consumption.

Unfortunately, both cumulative and daily consumption are measured with considerable error. As a result, any effect observed for one may be wholly or partially due to the other, even if the other has little or no apparent effect.

Repeated measures

One costly but effective method for reducing the degree of proxy-variable error in measuring time-dependent variables is to take repeated (serial) measurements over the follow-up period and ask subjects to report their pre-baseline history of such variables at the baseline interview. In our example, subjects could be asked about their age at first use and level of consumption at different ages for coffee and cigarettes; they could then be recontacted every year or two to assess their current consumption. Of course, not all subjects may be willing to cooperate with such active follow-up, but the penalties of some extra loss may be far outweighed by the benefit of improved measurement accuracy.

Errors in assessing incidence

An important form of measurement error in assessing incidence is misdiagnosis of the outcome event. In the AIDS example, a false-positive diagnosis of AIDS would result in underestimation of incubation time, whereas a false-negative diagnosis would result in overestimation. In the present example, false-positive errors would result in overestimation of myocardial infarction rates, whereas false-negative errors would result in underestimation. These errors will be of particular concern when the study depends on existing surveillance systems or records for detection of outcome events.

There are special cases in which the errors will induce little or no bias in estimates, provided the errors have little effect on the person-time observed. If the only form of misdiagnosis is false-negative error, the proportion of outcome events missed in this fashion is the same across cohorts, and if there is no follow-up bias, then the relative-risk estimates will not be distorted by the underdiagnosis. Suppose in our example that all recorded myocardial infarction events are true myocardial infarctions, but that in each subcohort 10 per cent of myocardial infarctions are missed. The myocardial infarction rates in each subcohort will then be underestimated by 10 per cent; nevertheless, if we consider any two of these rates, say R_0 and R_5 , the observed rate ratio will be:

$$\frac{0.9R_5}{0.9R_0} = \frac{R_5}{R_0}$$

which is undistorted by the underdiagnosis of myocardial infarction. Nonetheless, if coffee primarily induced 'silent' myocardial infarctions and these were the most frequently undiagnosed events, the effect of coffee would be underestimated.

Analogously, if the only form of misdiagnosis is false-positive error, the rate of false positives is the same across cohorts, and if there is no follow-up bias, then rate differences will not be distorted by the overdiagnosis. Suppose that the rate of false positives in our example is R_f in all subcohorts; then, if we consider any two true rates, say R_0 and R_5 , the observed rate difference will be:

$$(R_5 + R_f) - (R_0 + R_f) = R_5 - R_0$$

which is undistorted by the overdiagnosis of myocardial infarction. However, if there is non-differential underdiagnosis of myocardial infarction, as is probably the case in our example, the rate difference will be underestimated.

Specification validity

As noted earlier, the use of a statistical method based on an incorrect model (specification error) can lead to bias in estimates and improper performance of statistical tests and interval estimates. All statistical techniques, including non-parametric methods, must assume some sort of model for the process generating the data; however, in the absence of randomization or random sampling, it will rarely be possible to identify a 'correct' sampling model. In addition, structural assumptions are rarely (if ever) exactly satisfied. Thus, some specification error should be expected. As before, minimization of specification error must rely on checking the model against the data and against background information about the processes generating the data.

Recall that the unadjusted rate ratio estimates for five-cup-a-day versus never-drinkers is 1.22 in the present example, with 95 per cent confidence limits of 1.00 and 1.49, and a p -value of 0.05. Suppose that these figures were obtained by conventional person-time methods (Rothman et al. 2008, chapter 14). These methods are based on a binomial sampling model for the number of cases who drank five cups a day at baseline, given the combined total number of cases among five-cup-a-day and never-drinkers. In our example, the validity of this model depends on the assumption that the myocardial infarction rate remains constant within subcohorts over the follow-up period. It follows that the model (and hence the statistics given earlier) cannot be valid in our example; the subcohort members grow older over the follow-up period, and hence the myocardial infarction rates must increase with follow-up time.

The invalidity just noted can be rectified by stratifying either on follow-up time or the variable responsible for the change in rates over follow-up time (here, age). The stratification need only be fine enough to ensure that the myocardial infarction rate change within strata is negligible over follow-up. As noted earlier, however, we must also adjust for smoking and perhaps other factors responsible for confounding or follow-up bias. If we stratify finely enough to remove all the bias from these sources, the resulting estimates would be undefined or so unstable that they would tell us nothing about the association of coffee and myocardial infarction.

The standard solution to such problems is to compute adjusted estimates using regression models. These are structural models representing a set of assumptions (usually rather strong ones) about the joint effects of the study variables. Such models allow estimates and tests to be extracted from what would otherwise be hopelessly sparse data, at a cost of a greater risk of bias arising from violations of the assumptions underlying the models (Robins and Greenland 1986). For further details of cohort modelling, see Breslow and Day (1987), Hosmer and Lemeshow (2000), Kelsey et al. (1996), Checkoway et al. (2004), Jewell (2004), and Greenland (2008a, 2008b).

Summary of cohort example

The example used in this subsection provides an illustration of the most common threats to the validity of effect estimates from cohort studies. The unadjusted estimates of the effect of coffee on myocardial infarction will be confounded by many variables (such as smoking), and there will be follow-up bias. As a result, the number of variables that must be controlled is too large to allow adequate control using only stratification. The true functional dependence of myocardial infarction rates on coffee and the confounder is unknown, so that estimates based on multivariate models are likely to be biased. Even if this bias is unimportant, our estimates will remain confounded because of our inability to measure the key confounders accurately. Finally, our inability to summarize coffee consumption accurately would further bias our estimates, making it impossible to separate acute and chronic effects of coffee use reliably.

Given that there are several sources of bias of unknown magnitude and different directions, it would appear that no conclusions about the effect of coffee could be drawn from a study such as the one described in the preceding, other than that coffee does not appear to have a large effect. This type of result—inconclusive,

other than to rule out very large effects—is common in thorough epidemiological analyses of observational data. In particular, inconclusive results are common when the data being analysed were collected for purposes other than to address the hypothesis at issue, for such data often lack accurate measurements of key variables.

Special issues in case-control studies

The practical difficulties of cohort studies have led to extensive development of case-control study designs. The distinguishing feature of such designs is that sampling is intentionally based on the outcome of individuals. In a population-based or population-initiated case-control study, one first identifies a population at risk of the outcome of interest, which is to be studied over a specified period of time or risk period. As in a cohort study, one attempts to ascertain outcome events in the population at risk. Nevertheless, unlike a cohort study, one selects persons experiencing the outcome event (cases) and a 'control' sample of the entire population at risk for ascertainment of exposure and covariate status.

In a case-initiated case-control study, one starts by identifying a source of study cases (e.g. a hospital emergency room is a source of myocardial infarction cases). One then attempts to identify a population at risk such that the source of cases provides a random or complete sample of all cases occurring in this population. Study cases recruited from the source occur over a risk period; controls are selected in order to ascertain the distribution of exposure in the population at risk over that period. Case-control studies may also begin with an existing series of controls (Greenland, 1985). Regardless of how a case-control study is initiated, evaluation of validity must ultimately refer to a population at risk that represents the target of inference for the study.

Relative-risk estimation in case-control studies

The control sample may or may not be selected in a manner that excludes cases. If persons who become cases over the risk period are ineligible for inclusion in the control group (as in traditional case-control designs), a 'rare disease' assumption may be needed to estimate relative risks from the case-control data. In contrast, if persons who become cases over the risk period are also eligible for inclusion in the control group (as in newer case-control designs), the rare disease assumption can be discarded. These points are discussed in the textbooks cited at the beginning of this chapter.

The basics of case-control estimation will be illustrated using the following example. We wish to study the effect of coffee drinking on rates of first myocardial infarction and we have selected a population for study (e.g. all residents aged 40–64 in a particular town) over a 1-year risk period. At any point during the risk period, the population at risk comprises persons in this selected population who have not yet had a myocardial infarction.

Suppose that the average number of never-drinkers in the population at risk was 20,000 over the risk period, the average number of five-cup-a-day drinkers was 10,000, there were 120 first myocardial infarctions among never-drinkers, and there were 90 first myocardial infarctions among five-cup-a-day drinkers. Then, if one observed the entire population without error, the

estimated rates among never-drinkers and five-cup-a-day drinkers would be:

$$\frac{120}{20,000 \text{ person-years}} = \frac{90}{10,000 \text{ person-years}}.$$

Thus, if we observed the entire population, the estimated rate ratio would be:

$$\frac{90 / 10,000 \text{ person-years}}{20,000 \text{ person-years}} = \frac{90 / 120}{10,000 / 20,000 \text{ person-years}} = 1.50.$$

This estimate depends on only two figures: the relative prevalence of five-cup-a-day versus never-drinkers among cases (90/120), and the same relative prevalence in the person-years at risk (10,000/20,000). These two relative prevalences are often called the case exposure odds and the population exposure odds.

The first relative prevalence (numerator) could be estimated by interviewing an unbiased sample of all the new myocardial infarction cases that occur over the risk period, and the second relative prevalence (denominator) could be estimated by interviewing an unbiased sample of the population at risk over the risk period. The ratio of relative prevalences from the case- and control-sample interviews would then be an unbiased estimate of the population rate ratio of 1.50. This estimate is called the sample odds ratio.

Three points about the preceding argument should be carefully noted. First, no rare disease assumption was made. Second, the control sample of the population at risk was accumulated over the entire risk period (rather than at the end of the risk period); such sampling is called density sampling (Rothman et al. 2008, chapter 8) or risk-set sampling (Breslow and Day 1987). Third, because of the density sampling, someone may be selected for the control sample, and yet have a myocardial infarction later in the risk period and become part of the case sample as well. Methods for carrying out density sampling can be found in the textbooks cited at the beginning of this chapter.

Validity conditions in case-control studies

The primary advantages of case-control studies are their short time frame and the large reduction in the number of subjects needed to achieve the same statistical power as a cohort study. The primary disadvantage is that more conditions must be met to ensure their validity (in addition to the four listed in the cohort study example), and hence, there are more opportunities for bias to arise.

Suppose that our case-control study data yield an unadjusted rate-ratio estimate (odds ratio) of 1.50, with 95 per cent confidence limits of 1.00 and 2.25. The following series of conditions would be sufficient for the validity of this figure as an estimate of the effect of drinking five cups of coffee a day (versus none) on the myocardial infarction rate:

- (C) *Comparison validity*—if five-cup-a-day drinkers in the population at risk had instead drunk no coffee, their distribution of myocardial infarction events over time would have been approximately the same as the distribution among never-drinkers.
- (F) *Follow-up validity*—within each subpopulation defined by coffee use, censoring risk (i.e. population membership ended

by an event other than myocardial infarction, such as emigration or death from another cause) is not associated with myocardial infarction risk.

(Se) *Selection validity*—this has two components:

1. *Case-selection validity*—if one studies only a subset of the myocardial infarction cases occurring in the population over the risk period (e.g. because of failure to detect all cases), this subset provides unbiased estimates of the prevalence of different levels of coffee use among all cases occurring in the population over the risk period.
2. *Control-selection validity*—the control sample provides unbiased estimates of the prevalences of different levels of coffee use in the population at risk over the risk period.

(Sp) *Specification validity*—the distribution of myocardial infarction events over time in the subpopulations can be closely approximated by the statistical model on which the estimates are based.

(M) *Measurement validity*—all measurements of variables used in the analysis closely approximate the true values of the variables.

Issues of comparison validity, follow-up validity, specification validity, effect modification, and generalizability in case-control studies parallel those in follow-up studies, and so will not be discussed here. Case-control studies are vulnerable to certain problems of measurement error that are less severe or do not exist in prospective cohort studies. We shall discuss these problems first, and then examine selection validity and modelling. Finally, we shall briefly discuss analogous issues in retrospective cohort studies.

Retrospective ascertainment

A special class of measurement errors arises from the retrospective ascertainment of time-dependent variables; that is, attempting to measure past values of the variables. Retrospective ascertainment must be based on individual memories, existing records of past values, or some combination of the two. Therefore, such ascertainment usually suffers from faulty recall, missing or mistaken records, or lack of direct measurements in existing records.

Retrospective ascertainment may be an important component of a cohort study. For example, the cohort study of coffee and myocardial infarction discussed earlier could have been improved by asking subjects about their coffee use and smoking prior to the start of follow-up. This information would allow one to construct better cumulative indices than could be constructed from baseline consumption alone, although the resulting indices would still incorporate error due to faulty recall.

Unless records of past measurements are available for all subjects, measurements on cases and controls must be made after the time period under study as subjects are not selected for study until after that period. Thus, unlike cohort studies, most case-control studies of time-dependent variables depend on retrospective ascertainment. Considering our example, there may be much more error in determining daily coffee consumption ten years before interview than one month before interview; one might then expect case-control studies to be more accurate for studying acute effects than for studying chronic effects. Nonetheless, if acute

and chronic effects are heavily confounded, the elevated inaccuracies of long-term recall will make it impossible to disentangle short-term from long-term effects. As illustrated earlier, this confounding can arise in a cohort study. Nevertheless, in a cohort study, such confounding can be minimized by taking repeated measurements. In contrast, such confounding would be unavoidable in a case-control study based on recall, even if detailed longitudinal histories were requested from the subjects.

The preceding observations should be tempered by noting that some case-control studies have access to exposure measurements of the same quality as found in cohort studies and that the exposure measurements in some cohort studies may be no better than those used in some case-control studies. For example, a cohort study in which measurements are derived by abstracting routine medical records would suffer from no less measurement error than a case-control study in which measurements are derived by abstracting the same records.

Outcome-affected measurements

One common potential problem in case-control studies is outcome-affected recall, often termed *recall bias*. This term refers to the differential measurement error that originates when the outcome event affects recall of past events. Examples arise in case-control studies of birth defects, for instance. If the trauma of having an affected child either enhances recall of prenatal exposures among case mothers or increases the frequency of false-positive reports among them, estimates of relative risk will be upwardly biased by effects of the outcome on case recall. This bias may be counterbalanced by other biases, such as recall bias among controls, making the final direction and magnitude of bias due to faulty measurements hard to predict (Drews and Greenland 1990).

One method commonly proposed for preventing bias due to outcome-affected recall is to restrict controls to a group believed to have recall similar to the cases. Unfortunately, one usually cannot tell to what degree this restricted selection corrects the bias from outcome-affected recall. Even more unfortunately, one usually cannot tell if the selection bias produced by such restriction is worse than the recall bias one is attempting to correct (Swan et al. 1992; Drews et al. 1993).

A problem similar to outcome-affected recall can occur when the outcome event affects a psychological or physiological measurement. This is of particular concern in case-control studies of nutrient levels and chronic disease. For example, if colon cancer leads to a drop in serum retinol levels, the relative risk for the effect of serum retinol will be underestimated if serum retinol is measured after the cancer develops. Errors of this type can be viewed as proxy-variable errors in which the post-outcome value is a poor proxy for the pre-outcome value of interest.

Selection validity

Selection validity is straightforward to understand but can be extraordinarily difficult to verify. A violation of the selection validity conditions is known as selection bias. Many case-control designs and field methods are devoted to avoiding such bias (Kelsey et al. 1996; Koepsell and Weiss 2003; Rothman et al. 2008, chapter 8).

In some instances, it may be possible to identify a factor or factors that affect the chance of selection into the study. If in such instances we have accurate measurements of one of these factors,

we can stratify on (or otherwise adjust for) the factor and thereby remove the selection bias due to the factor. Because of this possibility, some authors classify selection bias as a form of confounding. Nevertheless, there are some forms of selection bias that cannot be removed by adjustment. These points will be illustrated in the following subsections.

Case-selection validity

Case-selection bias can be minimized (although may still be large due to non-participation) if one can identify every case that occurs in the population at risk over the risk period. This requires a surveillance system for the outcome of interest, such as a population-based disease registry. In our coffee-myocardial infarction example, we would probably have to construct a myocardial infarction surveillance system from existing resources, such as emergency room admission records, ambulance service records, and paramedic records.

Even if all cases of interest can be identified, selection bias may arise from failure to obtain information on all the cases. In our example, many cases would be dead before interview was possible. For such cases, there are only two alternatives: attempt to obtain information from some other source, such as next of kin or co-workers, or exclude such cases from the study. The first alternative increases measurement error in the study. The second alternative will introduce bias if coffee affects risk of fatal and non-fatal myocardial infarction differently, or if coffee affects risk of myocardial infarction survivorship. To illustrate, suppose that coffee drinking reduced one's chance of reaching the hospital alive when a myocardial infarction occurred. Then, the prevalence of coffee use among myocardial infarction survivors would under-represent the prevalence among all myocardial infarction cases. Underestimation of the rate ratio would result if fatal myocardial infarction cases were excluded from the study.

It might seem possible to remove the case-selection bias in this example by redefining the study outcome as non-fatal myocardial infarction. This does not remove the bias, however; it only leads to its reclassification as a bias due to differential censoring (here classified as a form of follow-up bias). In a study of non-fatal myocardial infarction, fatal myocardial infarction is a censoring event associated with risk of non-fatal myocardial infarction; if fatal myocardial infarction is also associated with coffee use, the result will be underestimation of the rate ratio for non-fatal myocardial infarction. More generally, it is usually not possible to remove bias by placing restrictions on admissible outcomes.

Unfortunately, exclusion is the only alternative for cases that refuse to participate or cannot be located. In our example, if such cases tend to be heavier coffee users than others, underestimation of the rate ratio would result. However, suppose that, within levels of cigarette use, such cases were no different from other cases with respect to coffee use. Then, adjustment for smoking would remove the selection bias induced by refusals and failures to locate cases. (Of course, such adjustment would require accurate smoking measurement, which is a problem in itself.)

Bias that arises from failure to detect certain cases is sometimes called detection bias. If our surveillance system used only hospital admissions, many out-of-hospital myocardial infarction deaths would be excluded, and a detection bias of the sort described here could result.

Control-selection validity

Control-selection bias can be minimized (although may still be large due to non-participation) if one can potentially identify every member of the population at risk at every time during the risk period. In such a situation, one could select controls with one of many available probability sampling techniques, using the entire population at risk as the sampling frame. Unfortunately, such situations are exceptional.

Many studies attempt to approximate the ideal sampling situation through use of existing population lists. An example is control selection by random digit dialling; here, the list (of residential telephone numbers) is not used directly but nevertheless serves as a partial enumeration of the population at risk. This list excludes people without telephone numbers. In our example, if people without telephones drink less coffee than people with telephones, a control group selected by random digit dialling would over-represent coffee use in the population at risk. The result would be underestimation of the rate ratio.

One could redefine the population at risk in the previous example so that the telephone-related selection bias did not exist by restricting the study to persons with telephones. This would require excluding persons without telephones from the case series. The resulting relative-risk estimate would suffer no selection bias. The only important penalty from this restriction is that the resulting estimate might apply only to the population of persons with telephones, which is a problem of generalizability rather than a problem of selection validity. In a similar fashion, it is often possible to prevent confounding or selection bias by placing restrictions on the population at risk (and hence, the control group). In such instances, however, one must take care to apply the same restrictions to the case series and avoid using restrictions based on events that occur after exposure (Poole 1999; Rothman et al. 2008, chapter 8).

Even if all members of the population at risk can be identified, selection bias may arise from failure to obtain information on all people selected as controls. The implications are the reverse of those for case-selection bias. In our example, if controls who refuse to participate or cannot be located tend to be heavier coffee users than other controls, overestimation of the rate ratio would result. This should be contrasted with the underestimation that results from the same tendency among cases.

More generally, one might expect an association of selection probabilities with the study variable to be in the same direction for both cases and controls. If so, the resulting case- and control-selection biases would be in opposite directions and so, to some extent, they would cancel one another out, although not completely. To illustrate, suppose that among cases the proportions who refuse to participate are 0.05 for five-cup-a-day drinkers and 0.02 for never-drinkers, and among controls the analogous proportions are 0.20 and 0.10. These refusals will result in the odds of five-cup-a-day versus never-drinkers among cases being underestimated by a factor of $0.95/0.98 = 0.97$; this in turn results in a 3 per cent underestimation of the rate ratio. Among controls, the odds will be underestimated by a factor of $0.80/0.90 = 0.89$; this results in a $1/0.89 = 1.12$, or a 12 per cent overestimation of the rate ratio. The net selection bias in the rate ratio estimate will then be $0.97/0.89 = 1.09$, or 9 per cent overestimation.

For further discussions of control-selection validity, see the textbooks cited in the beginning of this chapter, and also Savitz

and Pearce (1988), Schlesselman (1992), Swan et al. (1992), and Wacholder et al. (1992).

Matching

In cohort studies, matching refers to selection of exposure subcohorts in a manner that forces the matched factors to have similar distributions across the subcohorts. If the matched factors are accurately measured and the proportion lost to follow-up does not depend on the matched factors, cohort matching can prevent confounding by the matched factors, although there are statistical reasons to control the matched factors in the analysis (Weinberg 1985).

In case-control studies, however, matching refers to selection of subjects in a manner that forces the distribution of certain factors to be similar in cases and controls. Because the population at risk is not changed by case-control matching, such matching does not by itself prevent confounding by the matched factors. In fact, it is now widely recognized that case-control matching is a form of selection bias (Glymour and Greenland 2008; Rothman et al. 2008, chapter 11). This bias can be removed by adjusting for the matching factor; to the extent the factor has been closely matched and accurately measured, this adjustment also controls for confounding by the factor.

As an example, suppose that our population at risk is half male, that the men tend to drink less coffee than the women, and that about 75 per cent of our cases are men. Unbiased control selection should yield about 50 per cent men in the control group. However, if we matched controls to cases on gender, about 75 per cent of our controls would be men. Because men drink less coffee than women and men would be over-represented in the matched control group, the matched control group would under-represent coffee use in the population at risk. Note, however, that matching does not affect the gender-specific prevalence of coffee use among controls, and so the gender-specific and gender-adjusted estimates would be unaffected by matching. In other words, the selection bias produced by matching could be removed by adjustment for the matching factor.

The conclusion to be drawn is that matching can necessitate control of the matching factors. Thus, in order to avoid increasing the number of factors requiring control unnecessarily, one should limit matching to factors for which control would probably be necessary anyway. In particular, matching is usually best limited to known strong confounders, such as age and gender in the preceding example (Rothman et al. 2008, chapter 11).

More generally, the primary theoretical value of matching is that it can sometimes reduce the variance of adjusted estimators. However, there are circumstances in which matching can facilitate control selection and so is justified on practical grounds. For example, neighbourhood controls may be far easier to obtain than unmatched general population controls. In addition, although neighbourhood matching would necessitate use of a matched analysis method, the neighbourhood-matched results would incorporate some control of confounding by factors associated with the neighbourhood (such as socioeconomic status and air pollution).

Special control groups

It is not unusual for investigators to select a special control group that is clearly not representative of the population at risk if they

can argue that: (1) the group will adequately reflect the distribution of the study factor in the population at risk; or (2) that the selection bias in the control group is of the same magnitude of (and so will cancel with) the selection bias in the case group. The first rationale is common in case-control studies of mortality in which persons dying of other selected causes of death are used as controls; in such studies, selection validity can be assured only if the causes of death of controls are unrelated to the study factor. The second rationale is common in studies using hospital cases and controls; in particular, selection validity can be assured in such studies if the control conditions are unrelated to the study factor, and the study disease and the control conditions have proportional exposure-specific rates of hospital admission (Schlesselman 1992).

Selection into a special control group usually requires membership in a small and highly select subset of the population at risk. Thus, use of a special control group requires careful scrutiny for mechanisms by which the study factor may influence entry into the subset. See Schlesselman (1992) and Kelsey et al. (1996) for discussions of practical issues in evaluating special control groups, and Rothman et al. (Rothman et al. 2008, chapter 8) for validity principles in mortality case-control studies (so-called proportionate mortality studies).

Case-control modelling

The most popular model for case-control analysis is the logistic model. Details of logistic modelling for case-control analysis are covered in many textbooks, including Breslow and Day (1980), Schlesselman (1992), Kelsey et al. (1996), Hosmer and Lemeshow (2000), and Jewell (2004), and Greenland (2008b).

One important aspect of case-control modelling is that matched factors require special treatment. For example, suppose that matching is done on age in 5-year categories and age is associated with the study exposure. To control for the selection bias produced by matching, one must either employ conditional logistic regression with age as a stratifying factor, or else enter indicator variables for each age-matching category into an ordinary logistic regression (the latter strategy has the drawback of requiring about ten or more subjects per age stratum to produce valid estimates). Simply entering age into the model as a continuous variable may not adequately control for the matching-induced bias.

Summary of case-control example

The example in this subsection provides an illustration of the most common threats to validity in case-control studies (beyond those already discussed for cohort studies). After adjustments for possible confounding and follow-up bias (along the lines described for the cohort study), there may still be irremediable selection bias, especially if we use only select case groups (e.g. myocardial infarction survivors) or control groups (e.g. hospital controls). In addition, retrospective ascertainment will lead to greater measurement error than prospective ascertainment, and some of this additional error may be differential.

Given the even greater number of potential biases of unknown magnitude and different directions, it would appear that (as in the cohort example) no conclusions about the effect of coffee could be drawn from a study such as the one described, other than that coffee does not have a large effect. Again, this is a common result in thorough epidemiological analyses of observational data.

Special issues in retrospective cohort studies

Two major types of cohort studies can be distinguished depending on whether members of the study cohort are identified before or after the follow-up period under study. Studies in which all members are identified before their follow-up period are called *concurrent* or *prospective* cohort studies, and studies in which all members are identified after their follow-up period are called *historical* or *retrospective* cohort studies.

Similar to case-control studies, retrospective cohort studies often require special consideration of retrospective ascertainment and selection validity. In particular, retrospective cohort studies that obtain exposure or covariate histories from post-event reconstructions are vulnerable to bias from outcome-affected measurements. Suppose, for example, that a study of cancer incidence at an industrial facility had to rely on company personnel to determine the location and nature of various exposures in the plant during the relevant exposure periods. If these personnel were aware of the locations at which cases worked (as when a publicized 'cluster' of cases has occurred), biased exposure assessment could result. Such problems can also occur in a prospective cohort study if exposure or covariate histories are based on post-event reconstructions.

Retrospective cohort studies can also suffer from selection biases analogous to those found in case-control studies. Suppose, for example, that a retrospective cohort study relied on company records to identify members of the cohort of plant employees. If retention of an employee's records (and hence identification of the employee as a cohort member) were associated with both the exposure and outcome status of the employee, the exposure-outcome association observed in the incomplete study cohort could poorly represent the exposure-outcome association in the complete cohort of plant employees.

Conclusion

Uncertainty about validity conditions is responsible for most of the inconclusiveness inherent in epidemiological studies. This inconclusiveness can be partially overcome when multiple complementary studies are conducted; that is, when new studies are conducted under conditions that effectively limit bias from one or more of the sources present in earlier studies. Ideally, after enough complementary studies have been conducted, each known or suspected source of bias might have been rendered unimportant in at least one study. If at this point all the study results appear consistent with one another (which is not the case for coffee and myocardial infarction, although the studies of smoking and lung cancer provide a good example), the epidemiological community may reach some consensus about the existence and strength of an effect.

Even in such ideal situations, however, one should bear in mind that consistency is not validity. For example, there may be some unsuspected source of bias present in all the studies, so that they are all consistently biased in the same direction. Alternatively, all the known sources of bias may be in the same direction, so that all the studies remain biased in the same direction if no one study eliminates all known sources of bias. Such problems can be addressed tentatively via sensitivity analysis or the more elaborate methods of risk analysis and bias analysis (Eddy et al. 1992;

Greenland and Lash 2008; Lash et al. 2009; VanderWeele and Arah 2011; Greenland 2014). For these and other reasons, many authors have warned that all causal inferences should be considered tentative, at least if drawn from observational epidemiological data alone, although such tentativeness does not in any way rule out interventions when it is clear that the probable cost of failing to act far outweighs the probable cost of intervention (Rothman 1988; Rothman et al. 2008, chapter 2).

Causation and causal inference

Katherine J. Hoggatt, Sander Greenland,
and Tyler J. VanderWeele

Introduction to causation and causal inference

This chapter offers an introduction to causal inference theory as relevant to public health research. Causal inference can be viewed as a prediction problem, addressing the question of what the likely outcome under one action versus an alternative action is. Although asking these types of questions is very natural, answering them requires careful thought in both the statement of the causal hypothesis and the techniques used to attempt an answer. This chapter discusses these complexities, with further discussion in Chapter 5.13. More thorough coverage of these issues can be found in chapters 2, 4, and 9 of Rothman et al. (2008).

The chapter reviews considerations that have been invoked in discussions of causality based on epidemiological evidence. It then describes the potential-outcome (counterfactual) framework for cause and effect, showing how measures of effect and association are distinguished in that framework. The framework illustrates problems inherent in attempts to quantify the changes in health expected under different actions or interventions. The chapter concludes with a discussion of how research findings may be translated into policy.

The study of cause and effect

Starting in childhood, people acquire a notion of cause and effect that is based on the observation of one event always or often following another. Children observe that flipping a switch consistently results in the light going on and readily assign a cause and effect interpretation to these relations. Nonetheless, such naïve equation of ‘variation in tandem’ with causation will too often conflate causation with mere association.

The emergence of modern science has led to increasingly sophisticated observational and experimental methods to distinguish causal from non-causal association, aided by formal theories of causation. A formal theory of causation facilitates application of deductive reasoning to the process of causal inference. Of great importance, it allows us to define precisely the difference between causation and association and gives guidance on how to pose causal questions and test causal hypotheses; it does not, however, provide a basis for ‘proving’ causality, nor can it model the entire process of causal inference.

As Hume (1739) realized and discussed at length, there is no deductive way to prove causality. Thus, causal inference can only be a speculative, inductive process whose output is a theory of cause and effect. Indeed, the history of science shows that all theories, including causal ones, are necessarily provisional and that future evidence may lead to rejecting previously ‘established’ causal relations (Kuhn 1970). A key feature of several formal theories of causation is that they provide comparative predictions about the consequences of alternative interventions (e.g. dietary supplementation versus none) rather than singular predictions of events assuming no intervention (e.g. forecasts of flu epidemics) (Greenland 2012).

Those working in public health or policy must often make decisions on how to proceed in the face of equivocal evidence. The question then arises of how to weigh the evidence in favour of cause and effect to determine, say, whether smoking should be banned in bars to prevent lung cancer in bar workers, whether pregnant women should be told to take folic acid to prevent neural tube defects in their offspring, or whether postmenopausal women should be prescribed hormone replacement therapy (HRT) to prevent heart disease. In each of these cases, the final decision by health or policy professionals was made in the absence of definitive proof of causality, relying instead on the imperfect evidence gleaned from scientific studies.

Because of its central importance, causal inference is often confused with the more complex process of rational decision-making. While causal inference is a crucial input to decision-making, decision-making also depends on the costs and benefits of the outcomes. For example, it is believed that banning smoking in bars is likely to have health benefits that will more than outweigh any negative economic impacts. This perceived imbalance favouring benefits over costs is a major basis for a proposed ban. In contrast, recommendations that doctors prescribe HRT for the prevention of heart disease must acknowledge that HRT could have serious side effects on women’s health. The recommendations are easily challenged if the costs are shifted according to individual preferences and values.

Such examples show that multiple effects should be considered when policymakers evaluate the evidence of cause and effect based on epidemiological studies. Nonetheless, most attempts to formalize the process of causal inference focus on single end points. This

single-end point view must be understood thoroughly before considering multiple end points.

Hill's considerations

Many authors have attempted to list considerations that should be weighed when advancing causal arguments. Among these, the best known in epidemiology are by Sir Austin Bradford Hill (Hill 1965), which are closely related to the considerations found in the first US Surgeon General's report on smoking and health (1964). Hill's article has been widely misinterpreted as providing necessary conditions ('criteria') for causation to be inferred; see Phillips and Goodman (2004) for a discussion of this and other misinterpretations. In Hill's own words, the considerations were not meant to be a checklist or set of criteria, but rather simply 'points to consider', namely: (1) strength, (2) consistency, (3) specificity, (4) temporality, (5) biological gradient, (6) plausibility, (7) coherence, (8) experimental evidence, and (9) analogy; we shall discuss each of these in turn. In fact, the only one of these considerations that is necessary is temporality (time order).

Strength

The strength of an association may be considered important because it is harder to explain away strong effects as complete artefacts of biases such as confounding. There is no general rule for how large an association needs to be to provide compelling evidence for an effect, but, for example, it has been reported that many epidemiologists would be sceptical of a identifying a new risk factor for cancer if its risk ratio were less than 3 (Taubes 1995). Nonetheless, there are many smaller associations that are generally agreed to reflect causal effects. This is in part because they have been replicated in a variety of populations using different designs and in part because of considerations other than strength. Examples include the association between smoking and heart disease and between environmental tobacco smoke and lung cancer. Similarly, there are several well-known examples of relatively strong non-causal associations. One example is the association between birth order and Down's syndrome: maternal ageing, which is strongly associated with infant birth order, has since been accepted as the actual cause of the syndrome responsible for the association. Sensitivity and bias analysis can be used along with external information to estimate or quantitatively speculate on the extent to which possible bias sources have affected the strength of an observed association (Greenland and Lash 2008; Lash et al. 2009; VanderWeele and Arah 2011; Greenland 2014).

Consistency

A consistent finding is an association reported across multiple populations, over time, and using different study designs. Although the presence of a consistent result is often taken as a compelling argument for causality, the argument can be specious; for example, an inverse association of beta-carotene with cancer was seen across epidemiological studies but failed to be replicated in subsequent randomized trials. Conversely, the absence of consistency does not imply the absence of a causal effect. Acute effects may be submerged in studies that examine only chronic exposure, and some agents may operate only in highly susceptible subpopulations. Nonetheless, consistency across studies of a similar design helps rule out chance as an explanation for an observed

association. Consistency across studies of different designs can provide evidence against specific biases but cannot rule out bias entirely unless all reasonably possible biases have been addressed.

Specificity

In Hill's formulation, specificity can refer either to a cause having a single effect or an effect having a single cause. The limitations of this criterion are apparent even in the case of smoking and lung cancer. Although the smoking and lung cancer association is stronger (on the ratio scale) than the association between smoking and, say, heart disease, there is general agreement today that smoking can increase the risk of many diseases, including heart disease and other cancers.

Specificity can strengthen a causal inference if a competing non-causal hypothesis would predict a non-specific association. For example, some have argued that screening for certain cancers is ineffective in and of itself for reducing cancer mortality, and the apparent protective effect after adjustment for lead-time reflects the fact that those people who choose to undergo regular screenings are generally more health conscious and therefore at a lower risk for cancer due to their 'healthy lifestyle'. If a specific screening instrument, say a mammogram, were shown to be associated with lower mortality from breast cancer but not lower mortality due to cancers in other sites, it could strengthen the inference that mammography is indeed useful in preventing deaths from breast cancer; this approach is sometimes referred to as one of using 'negative controls' (Lipsitch et al. 2010). Although such issues can in theory also be addressed via randomized trials, the controversy surrounding trials of mammography (Freedman et al. 2004) shows that in practice similar considerations will arise even with randomized treatment assignment.

Temporality

Temporality means that a cause must necessarily precede its effect. This positive assertion is inarguable, but it is also possible that in some instances a putative cause (X) is followed by the hypothesized effect (Y), whereas in other instances the putative cause (X) precedes and does cause the effect (Y). Thus an observation that Y preceded X in a specific case is not an argument against causality in cases where Y followed X. Temporality is a definitive criterion for non-causality only if we know that X *cannot* come before Y. Temporality is, however, a necessary condition for assertion of causality in any given case. If X and Y vary over time, it is also possible that there is feedback between such that both affect each other. If data are available on multiple measurements of these variables, contemporary methods from causal inference can help evaluate such feedback (Robins et al. 1999).

Biological gradient

A biological gradient is a dose-response relation between an exposure and an outcome. Though most epidemiologists think of a 'linear' or monotonic dose-response association as strengthening a causal inference, this need not be the case. There may be a sharp increase in risk for specific outcomes at low to moderate doses of a given exposure that tapers off at higher doses, or there may be no adverse effect until saturation of detoxification mechanisms is reached, resulting in increased risk only at higher doses.

Many substances show non-monotonic trends with outcomes in a manner consistent with their hypothesized biological effects; for example, very low and very high doses of certain vitamins may increase the risk of death, a fact consistent with what we know about the biological properties of these vitamins. In addition, an apparent monotonic dose–response relation (risk always increasing with exposure or risk always decreasing with exposure) does not prove the observed associations are genuine rather than artefacts of confounding. If an uncontrolled confounder is monotonically associated with the exposure and monotonically associated with the disease, an apparent dose–response relation between exposure and outcome could simply reflect the dose–response relation between the confounder and outcome (Weiss 1981). Sensitivity analysis can clarify the extent to which a dose–response relationship contributes to evidence of causality (Rosenbaum 2003).

Plausibility

A plausible association is one that conforms to the current scientific understanding of the relation between a putative cause and its effect. This understanding can be informed by other epidemiological studies, animal studies, biology, toxicology, etc. The limitation of plausibility as a criterion for assessing causality is that current scientific understanding can be incomplete or wrong. The observation that cholera occurs in outbreaks does not demonstrate that cholera is caused by miasmas, despite miasma theory being the dominant idea in the early nineteenth century for how infectious agents were transmitted.

Coherence

Hill used the term ‘coherence’ to mean that the hypothesized causal relation of exposure to disease is not in conflict with the current scientific understanding of the disease process. Hill emphasized that an absence of coherent information was not a strong argument against causality. If an observed association apparently conflicts with current scientific understanding of a disease process, it may be that the understanding is mistaken rather than that the association is non-causal. For example, at the time it was made, the observation that shallow inhalers of cigarette smoke had increased rates of lung cancer relative to deep inhalers seemed to contradict the understanding of lung cancer aetiology. Subsequent research on lung cancer, however, found that the cells affected by cigarette smoke tended to be in the upper respiratory tract, which was in fact consistent with the observed association for shallow inhalers.

Conversely, coherence is a very fallible argument in support of causality. The theory that the inverse association of beta-carotene with cancers observed in epidemiological studies represented a preventive effect was quite coherent with contemporary theories of antioxidants and cancer, but this theory was nonetheless refuted by subsequent randomized trials.

Experimental evidence

In modern discussions, ‘experimental evidence’ often refers to either human or animal experiments, which themselves are very different categories of evidence. This type of evidence may be limited or absent. For many exposures, human experimentation is impractical or unethical, and, for many disease processes, no suitable animal model exists.

Hill seemed to have a different notion of experiment in mind, however, one more akin to classical writers such as Mill (1862). Hill discussed the evidence for causality that can be obtained by examining the association between exposure and disease when the potentially harmful exposure has been reduced or removed. These types of before-and-after comparisons may provide compelling evidence, although they can mislead if there are uncontrolled time-varying confounders that drive the observed associations.

Analogy

Analogy refers to drawing inferences about the association between a given exposure and disease based on what is known about other exposure–disease relations. Based on what is known about the health effects of cigarette smoking, we might expect that inhalation of other combustibles (e.g. marijuana) would have similar effects, even in the absence of studies on the subject. Analogy can be a useful scientific tool for generating new hypotheses about disease processes; however, its utility for assessing causality is limited by the understanding and imagination of the scientist.

Summary

For reasons such as those just discussed, Hill and other critical thinkers have discouraged taking his ‘viewpoints’ as a checklist for causality. Hill’s considerations may be useful in generating testable hypotheses that can bear on a discussion of causality, but none of them is sufficient to justify a causal inference, and only one, temporality, is a necessary condition for claiming that an observed association is causal.

Despite the ongoing popularity of Hill’s considerations—sometimes in modified form—there is no general agreement on which considerations should be used or how they should be used in making causal inferences (Weed and Gorelic 1996; Kaufman and Poole 2000; Holman et al. 2001). Some have argued that such aids to inference amount to refined common sense, which if taken as rigid criteria may harm the inferential process (Lanes and Poole 1984; Phillips and Goodman 2004, 2006; Rothman et al. 2008, chapter 2). Others have used the considerations to develop general deductive formats for evaluating causal hypotheses (MacLure 1985; Weed 1986; Susser 1991). Finally, researchers may use different considerations or deploy them differently based on the specifics of the inferences being made, suggesting that, in practice, most of the considerations are more like values than objective inferential tools (Poole 2001).

Formal approaches to causal inference

Implicit in the discussion of causal considerations is the idea that there is a well-defined notion of what constitutes cause and effect. Perhaps the oldest non-circular set of definitions arises from the potential-outcome or counterfactual framework. The potential-outcome or counterfactual model (Rosenbaum 2002; Morgan and Winship 2007; Rothman et al. 2008 chapter 4; Pearl 2009) specifies what happens to individuals or populations under alternative actions or interventions and also makes explicit the problems in operationally defining causes (Greenland 2002, 2005; Hernán 2005). This model of causation is also useful in defining methodological concepts such as confounding; this is discussed further in Chapter 5.13 and also in chapter 4 of Rothman et al. (2008).

Potential outcomes and counterfactual causality

Causal inference can be viewed as a prediction problem. For example, a public health researcher may wish to predict how the rates of lung cancer among bar workers would change if an indoor smoking ban was enacted. The potential-outcome model allows us to formalize questions such as ‘Will a smoking ban decrease the rates of lung cancer in 10 years beyond what can be expected in the absence of a ban?’.

In discussions of potential outcomes, three components must be defined:

- ◆ A target of interest, either an individual or group, that will be the subject of the study of causation.
- ◆ A list of possible interventions or actions (x_0 , x_1 , etc.) that could have been applied to the target over some time span of interest.
- ◆ An outcome measure (Y) taken after implementation of the intervention or action.

If x_a is the action taken from among possible actions x_0, x_1, \dots, x_n , a potential-outcome model posits that there is a well-defined outcome, $Y(x_a)$, that would have followed from that specific action x_a . This outcome is often termed a ‘potential outcome’.

As an example, suppose the treatment of interest is sending to members of an insurance plan, on their fiftieth birthday, a mail-in home sampling kit to screen for stool blood, a possible indicator of colon cancer. Suppose $X = 1$ if the kit is supplied to a person, and $X = 0$ if not. Ordinary analyses might examine one outcome variable, such as $Y = 1$ if the person dies of colon cancer by age 60 and $Y = 0$ if the person does not die by this age. But a potential-outcome analysis considers one outcome variable for every treatment being compared: for $X = 1$, we consider the outcome $Y(1) = 1$ if the person dies of colon cancer by age 60 *when sent the kit* and $Y(1) = 0$ if the person does not die *when sent the kit*. Similarly, for $X = 0$ we consider the outcome $Y(0) = 1$ if the person dies of colon cancer by age 60 *when not sent the kit* and $Y(0) = 0$ if the person does not die *when not sent the kit*. Offering the kit is then beneficial for the person with respect to these outcomes if $Y(1) = 0$ but $Y(0) = 1$, which is to say if the person would not die of colon cancer by age 60 if sent the kit but *would so die* if the kit *was not sent*. Presumably, such a benefit would arise because the kit, if sent, would be received, used, and would lead to detection of and intervention for an otherwise fatal tumour.

The potential-outcome model is widely used in statistical discussions of causality, and it has become increasingly popular in epidemiology and other fields. Yet, it is not without controversy, largely because at most only one potential-outcome variable can be observed for each person. That observable potential outcome is the one corresponding to the treatment actually received; all the other potential outcomes are unobserved, and hence are ‘missing data’. Understandably, the incompleteness of the data under the model is upsetting to practitioners, and the inevitable missingness requires reconsideration of many conventional statistical methods. Such reconsiderations have, however, led to innovative methods for previously intractable problems, such as the estimation of effects of time-varying treatment regimens (Robins et al. 1999).

There are also a number of aspects of the model that are often misrepresented as limitations but are not. For example, the model does *not* require that outcomes be well defined for any possible intervention; it simply requires that the outcomes be well defined for those interventions of interest. If, in a study of motorcycle crash fatalities, we wish to estimate the effect of a helmet law mandating fines for non-use versus no law, we do not need to specify any other actions (such as a law mandating jail time for non-use). Also, and contrary to some misunderstandings, the potential-outcome model is not inherently deterministic: although the model is quite often introduced and taught using deterministic language, a potential outcome could instead be the parameter of a probability distribution, for example the probability of disease.

Causes and effects

The term ‘effect’ is sometimes used to specify the outcome of a causal process. A researcher may describe lung cancer or heart disease as two possible effects of cigarette smoking. A quantitative definition of an effect is a numerical contrast in outcome measures corresponding to different actions or interventions, for example, $Y(x_1)$ and $Y(x_0)$. The numerical contrast is called a *measure of effect*. In the earlier example, if x_1 is the absence of a helmet law and x_0 is the presence of a helmet law, then $Y(x_1) - Y(x_0)$ could be the fatality-rate difference for motorcycle crashes and $Y(x_1)/Y(x_0)$ could be the fatality-rate ratio.

Thus, under a potential-outcome model, an effect is a contrast in outcomes corresponding to *two* different actions in *one* single target. Effects must be defined with respect to a clearly specified alternative or reference condition. To say that smoking one pack of cigarettes a day increases the risk for lung cancer and heart disease would be incorrect without specifying the alternative: smoking one pack a day may be harmful relative to not smoking, the implicit reference condition, but may be protective relative to smoking two packs a day. Statements about the effects of causes can be ambiguous or meaningless unless both the index and reference actions are stated explicitly.

It follows that an action cannot be considered inherently causal, and it can only be deemed causal when the outcome associated with it is compared to the outcome associated with an alternative action. Consider a person with depression who is prescribed an antidepressant medication. The weeks following initiation of treatment are thought to be periods of increased risk for suicide. If this person commits suicide in the period following treatment initiation, some would say the antidepressant caused the suicide. Given that the person was depressed to begin with, it is possible that he would have committed suicide even if he had not been prescribed the medication, in which case the antidepressant did not cause the suicide in reference to the alternative of no prescription. If instead of being prescribed an antidepressant, however, the individual had been hospitalized, he may not have committed suicide, in which case the antidepressant treatment may be considered a cause of his suicide, but only in reference to the alternative action of hospitalization.

A second important point is that because an effect is a contrast in outcomes for one target, we can observe at most one of the actions and its corresponding outcome. The other treatments, which are not observed, are *counterfactual* (contrary to fact), and as a consequence their corresponding potential outcomes are not

observed; for example, $Y(x_0)$ is unobserved (missing data) for all persons receiving treatment x_1 . These alternative potential outcomes can only be estimated.

If the index and reference actions lead to identical outcomes, then the index action is said to have no effect on the target. When an action has an effect, describing it as causal or preventive depends on which outcome we are referring to. If smoking a pack a day for 20 years (versus none) causes an individual to die at age 70, then this smoking also prevents survival past age 70. In parallel, if not smoking prevents death at age 70 relative to smoking a pack a day for 20 years, it causes that individual to survive past age 70.

Confounding and measures of association

Our inability to observe the potential outcome of more than one action fundamentally limits our ability to make causal inferences. In any attempt to estimate a causal effect, at least one potential outcome, corresponding to a counterfactual action, must be estimated or predicted rather than measured. In practice, this is accomplished by measuring outcomes in other individuals who actually experience the reference action. In experiments and in cohort studies, these individuals are often called the control subjects.

As an example, on 1 July 2000, Florida weakened its existing motorcycle helmet use law to exempt individuals over the age of 21 who had at least US\$10,000 in insurance in case of an accident. To estimate the effect of weakening the helmet law in Florida, we could compare (contrast) the rates of motorcycle crash fatalities before and after the change. Instead of the fatality rate in 2001, had the law not been changed, we use the fatality rate in 1999 before the law changed. This is no longer a measure of effect, because it is not a contrast of the outcomes of two different actions in a single group. Instead, it is a *measure of association*, which is a contrast of outcomes in two or more different groups. We use this measure of association as a substitute for the corresponding measure of effect. The amount of *confounding* is the difference between the measure of association and the measure of effect that it is intended to represent.

Confounding is a serious threat to our ability to make causal inferences. Nonetheless, we can often determine factors that contribute to the difference between the measure of association and the measure of effect. In our example, these would be reasons why the motorcycle fatality rates in 1999 would differ from those in 2001, had the helmet law never changed. These factors are commonly known as *confounders*. When confounders are measured, analytic methods can be used to minimize the amount of confounding from those factors and thus strengthen our inferences. The most basic methods are based on stratifying the observations on values of these confounders. *Standardization* then averages across outcomes in the index and reference groups using a shared (standard) weighting scheme (Rothman et al. 2008). Other methods make special assumptions to combine measures of association across strata. In all these approaches, the resulting summary comparison across the strata is said to be *adjusted* for the confounders used to create the stratification.

An adjusted measure of association will be a good estimate for the desired measure of effect only insofar as we have controlled for (e.g. stratified on) the important confounding factors. If there are other factors that contribute to important differences between the

counterfactual (alternative) outcome and the observed outcome used as a substitute, then the measure of association will remain a biased estimate for the measure of effect. In the case of the helmet law and the motorcycle crash fatalities, one would have to ask if all the important factors contributing to changes in the rate of crash fatalities *other than the change to the helmet law* had been measured and properly controlled. To the extent we are uncertain or doubtful about our measurement and control of important confounders, we would have to doubt the validity of the adjusted association as an estimate of the measure of effect (see Chapter 5.13).

Practical uses of causal inference

Academic discussions of cause and effect often focus on the ‘effects’ of changes that have no realistic interpretation as actions (e.g. elimination of lung cancer) or actions that are not realistic options (e.g. achieving a ‘smoke-free society’). Even when discussions focus on the impact of feasible interventions, they are often based on unrealistic assumptions about their consequences, for example, assuming 100 per cent compliance with a given treatment or behaviour-modification programme.

As an extreme example, some discussions centre on the expected health impact if a given disease or outcome could be removed. Such discussions are irrelevant and often misleading for policy formulation. For example, in a discussion of the ‘burden of disease due to lung cancer’, a rough ranking of actions and questions from irrelevant and unrealistic to most relevant would be:

- ◆ Directly eliminating lung cancer (e.g. ‘How many deaths could be prevented if we could eliminate lung cancer?’).
- ◆ Removing risk factors for lung cancer (e.g. ‘How many deaths could be prevented if we could eliminate cigarette smoking?’).
- ◆ Applying an intervention to an entire population (e.g. ‘If we could implement a given smoking-cessation programme to the entire smoking population of a nation, how many deaths could be prevented?’).
- ◆ Applying an intervention that will produce a small change in risk behaviours in part of a population (e.g. ‘If we could implement a given smoking-cessation programme in a targeted group of motivated individuals, how many deaths could be prevented?’).

We will discuss each of these actions in turn.

Removing outcomes

Discussions of the burden of disease often focus on the expected change in population health that might be expected if certain diseases or outcomes could be removed from a population, for example, in discussions of survival if one could ‘eliminate’ a certain type of cause-specific mortality. For example, suppose Y represents cause of death, with $Y = y_1$ for death from myocardial infarction (MI) and $Y = y_0$ for death from other causes (‘competing risks’). An individual will eventually experience one but not both of these outcomes, so at least one must be counterfactual.

Now suppose Z represents years of survival past age 50. Z is a measure of the burden of MI among those who reach age 50. The value Z will take depends not only on the value of Y but also on how that value (y_1 or y_0) is brought about. Suppose a man with a sedentary lifestyle and poor diet died from an MI at age 54, so

that we observe $Z(y_1) = 4$ (the number of years lived past the age of 50). The value of $Z(y_0)$ would then be the number of years lived past age 50 *if the MI death had been prevented*. This value would depend critically on how the MI death was prevented. If the man had taken up a regimen of physical activity and a healthy diet in his twenties, $Z(y_0)$ could be considerably larger than $Z(y_1)$ because the regimen would lower his risk of many causes of death besides MI. If instead the MI death was prevented by medical care at the time the MI occurred, $Z(y_0)$ and $Z(y_1)$ may not differ by much because the man would remain at an increased risk for future MI, cancer, and other potentially fatal diseases.

When the outcomes are not directly manipulable, any prediction based on the hypothesized removal of the outcomes needs to consider not just the fact of the outcome removal but also the method used to remove it (Greenland 2002, 2005; Kalbfleisch and Prentice 2002; Hernán 2005; Hernán and VanderWeele 2011). Even if we can define a realistic intervention for removal of the outcome with few side effects, there is little basis to assume that removal of a particular outcome in a given group yields a risk profile similar to that for other individuals who did not have the intervention yet do not experience the removed outcome. Unfortunately, standard statistical procedures for analysing these types of data make the assumption that the risk profiles are similar (an assumption of ‘independent competing risks’). Thus, it is reasonable to expect that even if we can conceive of an intervention that will prevent a specific outcome, estimates of effect in light of this outcome removal will likely be biased if estimation is based on the experience of those who do not experience the outcome in the absence of the intervention. In sum, to estimate the effects of outcome removal, one must study successfully treated individuals.

Removing risk factors

Consider the debate on obesity and mortality. Numerous studies have reported increases in mortality associated with having a body mass index (BMI) over 30 (the cutpoint for obesity) relative to a ‘normal’ BMI of 20–24.9. Some authors have used these findings to ascribe a causal role for obesity in mortality and have gone on to assert that getting people to lose weight will save lives. But suppose not all individuals who go from a BMI of over 30 to a BMI of (say) 24 lose weight in the same way. Some might start exercising and eating more healthfully, in which case lower mortality may in fact result. Others might undergo gastric bypass surgery or become chronic users of amphetamines, each of which are known to confer some mortality risk.

Unfortunately, studies that examine only the association of BMI with mortality tell us nothing about the impact of different interventions to change BMI. To obtain a relevant causal inference, one must specify an intervention aimed at reducing BMI and then compare the mortality outcomes under that intervention to outcomes under a reference intervention (such as no intervention). The resulting measure of association, as an estimate of a measure of effect, would *not* be a contrast in outcomes of persons at different levels of BMI; it would be a contrast in outcomes under *specific interventions* among persons who started with the same BMI.

The very idea of the ‘health effects of BMI’ suffers from confusion of the effects of interventions (e.g. a diet and exercise regimen) with the downstream results of intermediate outcomes (e.g. changes in BMI). At best, mortality rates across BMI groups are averages taken across a range of *unknown* interventions that

brought about the observed BMI levels. As a consequence, comparisons of these rates correspond to comparing average outcomes under differing distributions of unknown interventions (VanderWeele and Hernán 2013), and even this limited interpretation holds only under very strong assumptions. A change in BMI is not an intervention, thus one cannot unambiguously define the causal effect of a change in BMI. A similar problem arises if one considers the effect on lung cancer incidence if more people were non-smokers. As with BMI, a researcher would need to specify an intervention (e.g. nicotine patches, hypnotherapy, medication, etc.) before discussing the possible result of getting smokers to quit.

When conceptualizing exposures in observational studies as interventions, as opposed to protocols in clinical trials, there are limitations to how detailed the description can be, making vagueness about the hypothetical intervention unavoidable (Robins and Greenland 2000). Nevertheless, moving away from thinking of outcomes such as BMI as potential causes—as opposed to intermediates—is necessary for making policy-relevant causal inferences from observational data.

A related problem arises in discussing the causal effects of personal characteristics. For example, considerable debate has surrounded the question of whether it is meaningful to speak about factors such as race or sex as being possible causes of effects (Holland 1986; Greenland 2005; Kaufman 2008; VanderWeele and Hernán 2012). Although it might seem natural to ask whether the risk of a disease like hypertension is affected by a person’s race, studies that contrast rates of hypertension in different racial groups do not adequately address this question. To ameliorate the racial disparities in hypertension, we would first need to identify feasible interventions. For this goal, discussing race as a cause is of no help, because changing the race of individuals is not a clearly defined action let alone a feasible intervention. Such associations can identify disparities but will usually not pinpoint their causes (Kaufman 2008).

Identifying and evaluating feasible interventions

Even when an exposure is an intervention, the discussion of its effects can be complicated if there is treatment non-compliance. In practice, apart from occasional mandates, treatments are only prescribed or recommended, therefore prescription or recommendation is all that can be studied and implemented. What a subject actually chooses to do in response to the assigned treatment is a function not only of the assignment but also of other factors, many if not most of which are infeasible to modify (such as the subject’s age).

If the researcher wishes to understand the effects of received treatment rather than treatment assignment, it is important to realize that received treatment is an outcome, not an intervention, and is thus subject to the problems described earlier for intermediate outcomes such as BMI. Special techniques are available for studying the effects of received treatment (e.g. instrumental variables, g-estimation; see Greenland 2000 and Greenland et al. 2008 for elementary discussions of these topics). Nonetheless, effects estimated by these techniques are those expected under ideal conditions and will likely overestimate the effects that will be seen in field implementation. The most relevant causal hypotheses for policymakers and health practitioners concern the changes

in outcome to be expected under the implementation of feasible interventions, subject to all their compliance problems.

Estimating field effects of feasible interventions is difficult but doing so at least avoids the unrealism and biases that arise from pretending that subject characteristics or behaviour are under direct or perfect control of health practitioners or society. In studying these types of interventions, the effect measure of interest will be a contrast in outcomes corresponding to different levels of the intervention (e.g. whether or not to fund a given programme), rather than the ‘received treatment’ discussed earlier. Thus the question is not what would happen if people were to comply with the intervention they were assigned, but rather what would result if people were offered a given treatment at a given cost.

Studies that address causal hypotheses about feasible interventions face profound methodological difficulties. If the intervention is not assigned at random (e.g. if individuals who participate in a given intervention are volunteers, and their outcomes are compared to those who chose not to participate), the resulting measure of association is likely to be confounded and will therefore be a poor estimate of the desired measure of effect. The measure of association can also be distorted due to refusals, loss to follow-up, and measurement error, among other things. These threats to validity are discussed in Chapter 5.13 and in epidemiological methods texts such as Rothman et al. (2008).

Problems in generalizing the results from a particular study to the target population of interest are not given detailed attention in many textbooks, yet they are of great concern for policymaking. The target populations for policy are always different from study populations, for at the very least the target population is defined in terms of future experience, whereas study results are always based on the past. Even if there are no time trends, however, factors such as the compliance rate and response to the intervention may depend on the characteristics of the individuals involved in a given study. The results from a study may therefore not be applicable to other populations, each of which may be composed of a different mix of individuals.

This problem of population heterogeneity of effect is sometimes framed as an issue of ‘effect measure modification’, meaning that the measure of the intervention effect depends on characteristics of the individual or the population (see Rothman et al. 2008, chapter 4). In theory, the solution is to identify factors responsible for the heterogeneity, stratify on these factors, estimate effect measures within the stratified groups, and predict the likely impact of an intervention in a target population by standardizing the stratified estimates based on the distribution of the factors in the target population. This approach is not wholly satisfactory, however, because it can be difficult to identify all the important sources of heterogeneity, and there are always severe data limitations on the number of factors that can be studied in this fashion.

From research to policy and beyond

This chapter has reviewed some of the considerations necessary in making causal inferences relevant to public health. These considerations are not crucial in all or even most studies, especially if the explicit goal of the study is to report associations and thus provide data for subsequent evaluations, rather than to estimate causal effects (Greenland et al. 2004). In fact, results from epidemiological studies are rarely the sole basis for policy decisions, although they

are important inputs for policy and judicial decisions. To name just a few examples, studies on the link between smoking and lung cancer have led to labelling of cigarette packs and bans on indoor smoking; results linking air pollutants to disease and mortality have informed emissions standards; and findings on the connection between vitamin deficiencies and adverse health outcomes have led to fortification of milk, cereals, and flour. In all these examples, decisions were based not only on multiple epidemiological studies but also on evidence from laboratory and clinical studies and considerations of mechanistic theories.

It is thus important for public health researchers as well as policymakers to understand the fundamentals of causal inference, especially the often neglected issues of defining meaningful and feasible interventions. It is equally important for researchers to understand that scientific research is done to inform policymaking, not to set policy, and that causal inference represents a synthesis of multiple evidence streams. Apart from perhaps outbreak investigations or large, well-executed randomized trials, no single study is capable of establishing a causal relation; furthermore, randomized trial populations must be reasonably representative of target populations in order to fully inform clinical or policy decisions. Those decisions should be based on a careful consideration of the entire relevant scientific and policy literature and must address cost–benefit considerations as well as purely scientific issues.

Systematic reviews and meta-analysis

Jimmy Volmink and Mike Clarke

Introduction to systematic reviews and meta-analysis

Reviewing and summarizing existing knowledge from studies that have addressed a particular topic (sometimes referred to as research, or evidence, synthesis) has long been recognized as an important scientific activity. At a meeting in 1884, Lord Rayleigh, a Professor of Physics at Cambridge University, noted, 'If, as is sometimes supposed, science consisted in nothing but the laborious accumulation of facts, it would soon come to a standstill, crushed, as it were, under its own weight. . . Two processes are thus at work side by side, the reception of new material and the digestion and assimilation of the old; and as both are essential we may spare ourselves the discussion of their relative importance' (Rayleigh 1885).

These remarks underscore the importance of understanding the cumulative nature of science, implying that new research should be guided by what is already known and that new research findings should be interpreted in the context of the totality of available evidence (Chalmers et al. 2002). In practice this means that new research should begin and end with an adequate review of other relevant research (Clark and Horton 2020; Clarke et al. 2010).

Reviews also play a critical role in guiding practitioners, policymakers, and consumers to make well-informed decisions and choices. The massive expansion in the volume of biomedical literature, beginning in the middle of the twentieth century, has made it increasingly difficult for healthcare decision-makers to keep up with the findings of individual studies. Reviews of the literature are thus important for taking stock of existing knowledge and making informed choices about healthcare and resource allocation (Mulrow 1995; Sackett et al. 1997; Chalmers and Glasziou 2009).

To the extent that they provide reliable summaries of research evidence, reviews can be extremely valuable. However, poorly conducted reviews drawing incorrect conclusions from the literature have the potential to cause serious harm to patients and populations, and waste much-needed resources (Chalmers 2003).

Rationale for systematic reviews

A number of obstacles to carrying out scientifically sound reviews have been identified. First, research reports are very widely dispersed and relevant papers may be hard to find. In the mid 1990s, it was estimated that some two million articles were

published annually in more than 20,000 biomedical journals (Mulrow 1995) and there have been further increases since then. Furthermore, other useful scientific information is distributed in the 'grey literature' (e.g. books, theses, conference abstracts government and company reports) and on the Internet. Added to this, access to research is often biased (Hopewell et al. 2007b, 2009; Dwan et al. 2008). For instance, studies with 'negative' or 'disappointing' findings are less likely to be published. If they are, they are less likely than 'positive' studies to be published in full, in journals that are widely read, or in English. This means that limiting one's efforts to easily accessible studies may result in an over-optimistic view of reality. Another problem is that studies addressing the same question frequently produce conflicting findings which will require explanation, and careful efforts to compare and contrast different studies. Such inconsistencies in findings can be due to factors such as differences in study characteristics (participants, interventions, and outcomes), flaws in study conduct, or reporting (bias) or random error (the play of chance). To address these challenges, sound methods to identify, assess, and synthesize study findings are needed.

Unfortunately, scientific rigour has not always received sufficient attention in the conduct of literature reviews. A seminal study published in the 1980s demonstrated that reviews published in leading medical journals failed to use scientific methods for synthesizing research evidence (Mulrow 1987). Subsequent research showed that these shortcomings were widespread, often leading to recommendations that were not based on the best available evidence, and to inadequate healthcare being offered with deleterious effects on health outcomes. For example, in the field of cardiovascular medicine it was found that poorly conducted research syntheses had contributed to substantial delays in adopting effective interventions, while allowing other interventions to remain in use long after research had demonstrated that they were ineffective or harmful (Antman et al. 1992). Similar findings have been documented across a range of healthcare fields (Egger et al. 2001; Chalmers 2003; Oxman et al. 2007).

In recent years, the 'systematic review' has emerged as a response to these deficiencies (Chalmers and Altman 1995; Glasziou et al. 2001; Higgins and Green 2011; Khan et al. 2011). Systematic reviews use systematic, explicit, and reproducible methods to identify relevant studies, assess the risk of bias in primary studies, extract information, and synthesize findings. Systematic reviews often employ statistical methods to combine data from similar

Table 5.15.1 Comparison of systematic and traditional reviews

Systematic review	Traditional review
States the methods of the review	Often does not state the methods of the review
Answers a focused question or tests a hypothesis; usually narrow in scope	May have a clear question but it often involves general discussion with no stated hypothesis; often very broad in scope
Attempts to locate all relevant studies to minimize publication and other biases	Usually does not attempt to locate all relevant studies
Uses explicit eligibility criteria to determine which studies will be included in the review to prevent selection bias on behalf of the reviewer	Usually does not specify why some studies are included and others excluded
Systematically appraises the methods of the included studies to determine possibility of bias in these studies and sources of heterogeneity between the study results	Often does not assess the risk of bias in the studies or acknowledge differences in their methods
Bases results on studies that are most methodologically sound	Often does not distinguish between methodologically sound and unsound studies
May combine study results statistically in a meta-analysis	Often does not pool results in a meta-analysis
Results illustrate true level of heterogeneity of data, allowing quantification of uncertainty	Results often presented in black and white terms without indicating uncertainty or variability

studies (known as meta-analysis) in order to obtain more precise estimates than those derived from the individual studies included in reviews. Table 5.15.1 provides a comparison of the typical characteristics of systematic versus more traditional reviews.

In recent years, systematic reviews have gained wide recognition as an essential tool for evidence-based decision-making in health-care (Petticrew 2001; McMichael et al. 2005; Lavis 2009; Dickersin 2010). For instance, when evaluating the effects of interventions they are considered as the ‘gold standard’, occupying the top of the ‘hierarchy of evidence’. This hierarchy is typically depicted in the form of a pyramid with expert opinion at its base, followed by various types of observational studies, then randomized trials and finally systematic reviews. Because the risk of bias decreases when moving from the bottom to the top of the pyramid, the position of systematic reviews in the hierarchy reflects the fact that they are regarded as the most reliable form of evidence. A further indication of their general acceptance into the mainstream comes from two other developments: funding agencies are beginning to require that investigators provide evidence from up-to-date systematic reviews that a new trial is justified, and some journals now require authors of new trials to report the findings from a systematic review which puts their trial into context (Clark and Horton 2010).

In this chapter, we describe the steps involved in conducting a systematic review: formulation of a review question, identification of relevant studies, extraction of data, assessment of bias in included studies, synthesis of the data, interpreting the evidence, and writing up and updating the review. Further details on each of these steps can be found in published handbooks and guidelines (Liberati et al. 2009; Higgins and Green 2011), as well as in various texts on systematic reviews (Glasziou et al. 2001; Borenstein et al. 2009; Higgins and Green 2011; Khan et al. 2011).

The review protocol

As should be the case for any new piece of scientific research, a systematic review begins with the preparation of a protocol in

which the objectives and proposed methods are documented. In a systematic review this is important for reducing bias that may result from reviewers making judgements during the review process that are influenced by their knowledge of individual study findings.

Publication of the review protocol in a publicly accessible register is encouraged (Liberati et al. 2009; *PLoS Medicine* Editors 2011; Stewart et al. 2012). This not only improves transparency and allows detection of any changes to the protocol that may have occurred during the process of the review, but also reduces the likelihood of unnecessary duplication of effort and facilitates peer review of the intended methods (Silagy et al. 2002; Straus and Moher 2010; Booth et al. 2011). PROSPERO, developed by the Centre for Reviews and Dissemination at the University of York, England (Booth et al. 2011) and the *Cochrane Database of Systematic Reviews* (<http://www.thecochranelibrary.com>) are examples of registers of systematic reviews. Certain funders, such as the National Institutes of Health Research in the United Kingdom and the Canadian Institutes of Health Research, now require that all systematic reviews they support are registered (Stewart et al. 2012).

Formulating the review question

The most critical step in preparing a systematic review is the formulation of a clearly defined question, since this influences all subsequent steps of the review. Review questions may address a wide variety of issues, such as the incidence or prevalence of disease (Pendlebury and Rothwell 2009), accuracy of a diagnostic test (Doust et al. 2004), disease aetiology (Renehan et al. 2008), effects of curative or preventive interventions (Siegfried et al. 2009), economic evaluations (Pérez Velasco et al. 2012), or disease prognosis (Damman et al. 2007). These questions typically lead to the search for, and synthesis of, quantitative studies.

Systematic reviews of qualitative studies, despite presenting some unique methodological challenges, are also possible and

are growing in popularity (Britten et al. 2002; Munro et al. 2007; Atkins et al. 2008). Such reviews tend to focus on the framing of a health problem (Mays 2005; Lavis et al. 2009) or explore barriers to, and facilitators of, policy or programme implementation (Innvaer 2002; Child 2012). These may be helpful for explaining why certain interventions do or do not work.

The review question may have a broad or narrow scope. For example, when evaluating the effects of interventions to promote adherence to therapy, a review could assess all interventions in any patient using chronic medication. Alternatively, the review question may be limited to a particular kind of intervention (e.g. economic support) in a particular group (e.g. adults) with a specific disease (e.g. tuberculosis) and explore a specific outcome (e.g. cure or treatment completion).

Decisions about a review's scope will be influenced by considerations such as the purpose, intended relevance and envisaged impact of the review, the theoretical, biological, and epidemiological rationale, and the potential for obtaining valid answers to the review question or for generalizing the findings of the review (O'Connor et al. 2011). Often, the scope will depend on the resources available for conducting the review. Although reviews with a broad scope tend to be more useful than those with a limited scope for generalizing findings across different participants, interventions, and settings, they may present a higher risk of heterogeneity ('mixing apples and oranges'), which can make it difficult to interpret their findings (O'Connor et al. 2011).

Regardless of how wide the intended scope of a review may be, it is always important to formulate the question as precisely as possible. The reason for this is that the question has a direct impact on all subsequent aspects of the review process, in particular the eligibility criteria for including or excluding studies and the efficiency of the search for relevant studies. A review question that is imprecise or unfocused may result in the reviewer finding a large amount of potentially relevant literature, which will take a long time to screen in order to find the truly relevant articles for answering the question.

A well-structured question for a review of the effects of an intervention will typically specify the following key components: participants (*population or problem*), *intervention* (or *indicator*),

comparator (control), and *outcome(s)* of interest. The acronym 'PICO' is therefore often used as a reminder of these specific aspects of the question and its use can be illustrated as follows: 'In patients receiving treatment for clinical tuberculosis (P) does a policy of direct observation of treatment (I) versus a policy of self-treatment (C) lead to different treatment success rates (O)?'

The PICO approach can also be used for formulating review questions that are not related to the benefits or harms of interventions. Regarding aetiology or risk, one might, for example, ask: 'Are women (P) who smoke during pregnancy (I) compared to women who do not smoke (C) more likely to give birth to children who develop asthma during the first 5 years of life (O)?'

Once a review question has been constructed, it can be converted into one or more specific review objectives. Thus, with reference to the first example of a review question given earlier, the objective could be: 'To compare directly observed therapy with self-administration of treatment on treatment success rates in patients receiving treatment for clinically active tuberculosis.'

Identifying relevant literature and setting eligibility criteria

The most time-consuming step of a systematic review is usually the identification of studies which should be included in the review. This requires the development of an efficient search strategy, a process which begins with the choice of study eligibility criteria.

Building on the defined review question and associated objectives, eligibility criteria for inclusion or exclusion of studies in the review can be specified. These eligibility criteria are usually defined in terms of the type of participants, interventions, and comparisons (and less frequently the outcomes). In addition to these 'PICO' components, the types of study to be included in the review are usually also specified at this stage. Describing each of these components in some detail will assist the development of the search strategy, as well as the selection of relevant studies. An example of this is provided in Box 5.15.1.

Defining the participants or problem (P)

Participants could be described in terms of sociodemographic characteristics, such as age, sex, ethnicity, and educational status,

Box 5.15.1 Study eligibility criteria specified in a review of adenoidectomy versus non-surgical management or tympanostomy tubes in children with otitis media

- ◆ (P) The participants included children up to 18 years of age diagnosed with otitis media.
- ◆ (I/C) Studies that compared adenoidectomy versus non-surgical management only (defined as watchful observation and medical treatment): adenoidectomy and unilateral tympanostomy tube versus unilateral tympanostomy tube only; and adenoidectomy with bilateral tympanostomy tubes versus bilateral tympanostomy tubes only.
- ◆ (O) The primary outcome was the proportion of time children had effusion, diagnosed with or without tympanometry. Secondary outcomes were occurrence of acute otitis media, occurrence of otitis media with effusion, and the mean hearing level. Occurrence of the condition was defined as the number of episodes per year, number of days per episode per year, and the proportion of children with recurrent episodes.
- ◆ (S) Only randomized trials were considered for inclusion and only those that had follow-up of participants of at least 6 months.

Source: data from Van den Aardweg MTA et al., Adenoidectomy for otitis media in children, *Cochrane Database of Systematic Reviews* 2010, Issue 1, Art. No.:CD0077810, Copyright © 2010 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

as well as the setting in which the study occurred (e.g. hospital or community based). It may also be important to provide a specific definition of the target health condition under consideration. Where restrictions based on population characteristics (e.g. people living in low- and middle-income countries) are used, these need to be explained clearly. It is often better to include studies covering a wide spectrum of participants, because differences across different groups can always be explored in the review at a later stage. If a narrow range of patients is specified at the outset of the review, there will be no such variability to explore at later stages of the review.

Defining the types of interventions (I) and comparisons (C)

For reviews of the effects of interventions, it is important to clearly define the intervention being evaluated: what is being delivered, at what intensity, how often, who delivers it, for how long, when it is delivered and what training was given to people involved in the delivery?

Reviewers also need to specify whether the intervention will be compared with an inactive or 'neutral' control intervention (e.g. placebo, standard care, no treatment) or an active control intervention (e.g. different regimen of the same drug or a different kind of therapy).

Defining the types of outcomes (O)

All outcomes that are relevant to end-users of the review, such as patients, healthcare practitioners, and policymakers, should ideally be included. For this reason, outcomes usually do not form part of the eligibility criteria for deciding whether or not an individual study should be included in the review. Reviewers are encouraged to include important outcomes even if they have not been addressed in the original studies, because this could help identify gaps in the evidence base that need to be addressed in future research.

Further, it may be necessary to consider whether the outcomes of interest are measured objectively (e.g. death or number of strokes) or subjectively as rated by clinician, patient, or carer (e.g. disability scales), and whether measuring instruments would have required validation. The timing of outcome measurement may also be important to define, for example, short-term compared to long-term outcomes.

It is advisable to separate outcomes into primary outcomes that are critical for informing decision-making (or that can be measured objectively) and secondary (additional) outcomes that may be of interest for other reasons (or that are less objectively assessed). Reviews should evaluate at least one desirable (beneficial) and one undesirable (adverse) outcome as both are important for making informed healthcare decisions. Various frameworks to evaluate adverse effects in systematic reviews have been proposed (Loke et al. 2007; Guyatt et al. 2011). Reviewers should also consider using pre-defined core outcome sets to help them to decide which outcomes to use in their review (Williamson et al. 2012; Kirkham et al. 2013).

Defining the study design (S)

Based on the review question, a determination needs to be made about the types of study design that are likely to provide the most

reliable answers. For instance, it may be appropriate to limit the review to randomized trials in the case of questions about the effects of an intervention, to cross-sectional studies for reviews of diagnostic accuracy, or to cohort studies if the intention is to answer a question about disease prognosis. Reasons for including and excluding specific study designs need to be made explicit in the review.

In the real world, researchers sometimes conduct reviews using study designs that are not ideally suited to a particular question, perhaps because more reliable studies do not exist. This can pose challenges to the interpretation of the evidence, because of inconsistency of the findings, which limits decision-making. The case of male circumcision as a public health intervention for the prevention of HIV acquisition in heterosexual men provides an instructive example of such a scenario. In 1995, a Cochrane Review commissioned by the World Health Organization assessed all 37 observational studies that had studied this relationship (Siegfried et al. 2005). Although many studies showed an association between male circumcision and HIV prevention, the review documented substantial between-study variation in the findings. This was particularly marked in studies conducted in the general population, as opposed to those conducted among high-risk groups. The authors, because of their concerns about residual confounding in these studies, concluded that the evidence available was insufficient to guide policy and that the findings of randomized trials should be awaited. A few years later, a Cochrane Review update (Siegfried et al. 2009) evaluated the results of the three trials which had been completed subsequent to the publication of the original review. It found strong evidence that medical male circumcision reduces the acquisition of HIV by heterosexual men by between 38 per cent and 66 per cent over 24 months, with a low incidence of adverse events. Fig. 5.15.1 presents the findings of the observational studies and trials conducted in the general population, showing the marked differences in consistency in their results, as well as the results of the subsequent randomized trials.

Search strategy

Once the study eligibility has been determined, the reviewer can proceed to the development of the search strategy. The aim should be to develop a search strategy which has high sensitivity (defined as the number of relevant reports identified divided by the total number of all relevant reports in existence) and high precision (i.e. the number of relevant reports identified divided by the total number of reports identified) (Lefebvre et al. 2011). In order to reduce the impact of reporting biases, it is important to search for articles published in any language, as well as those that are unpublished or available only in the grey literature (Hopewell et al. 2007c).

In the biomedical sciences, there are three key electronic sources of published reports of clinical trials: MEDLINE (<http://www.ncbi.nlm.nih.gov/pubmed>), EMBASE (<http://www.elsevier.com/online-tools/embase>), and CENTRAL (Cochrane Central Register of Controlled Trials) (<http://www.thecochranelibrary.com>). A comprehensive search strategy requires each of these databases to be searched (Lefebvre et al. 2011) and others as appropriate to the review. As these three databases tend to have a North American and European bias, it might also be worth searching other databases such as LILACS (Latin American Caribbean

Health Sciences Literature) (<http://lilacs.bvsalud.org/en/>) and African HealthLine (<http://www.nisc.co.za/databases?id=62>). It may also be important to include subject-specific databases, such as PsycINFO (www.apa.org/pubs/databases/psycinfo/index.aspx) (for psychology and related behavioural and social sciences), as well as Internet search engines, such as Google Scholar (<http://scholar.google.co.uk/>).

Strategies can be used to identify both free-text words in the database, and controlled terms (called MeSH, or Medical Subject Headings, in MEDLINE and Emtree in EMBASE) which are used as keywords. Search strategies need to include the key terms in the review question, and use the Boolean operators ('AND', 'OR') to produce a search that is most likely to find relevant studies. Because of the complexities inherent in designing search strategies, it is advisable to seek assistance from librarians or information specialists before embarking on a literature search (Lefebvre et al. 2011).

The next step in searching for relevant articles involves screening of reference lists of all studies identified from the electronic search, including previously published reviews, to identify any missed studies (Horsley et al. 2011). It is also legitimate to conduct handsearching of specific journals that are not indexed in electronic databases to make sure that no studies that meet the review inclusion criteria have been missed (Hopewell et al. 2007a). Finally, unpublished studies and 'grey literature' such as conference abstracts, research reports, policy documents, dissertations, book chapters, and personal correspondence, should be sought by contacting authors of identified papers and relevant organizations, including pharmaceutical companies and by searching websites (Hopewell et al. 2007c). It is also important to identify ongoing studies, for example, by searching prospective trials registers, as these may be needed for future updates of the review (Ghera et al. 2009).

Application of the search strategy typically identifies many (sometimes thousands of) potentially relevant papers. At this

stage, two reviewers should read the title and abstract of each report to determine whether the study should be included or excluded based on whether or not it meets the pre-specified eligibility criteria (Edwards et al. 2002). Where there is uncertainty, a copy of the full paper needs to be obtained for further scrutiny. The two reviewers should compare their results, and resolve any differences through consensus or by using a third person to arbitrate when required (Higgins and Deeks 2011). The search strategy should be carefully conducted to ensure reproducibility and its outcome clearly presented, ideally by means of a flowchart as recommended by PRISMA (Fig. 5.15.2) (Liberati et al. 2009).

Data collection and extraction

Deciding on what data to collect

The specific items of data to be collected from included studies will be influenced by the goals of the systematic review. However, the following items should generally be considered (Higgins and Deeks 2011):

- ◆ Eligibility of the study for inclusion or reason for exclusion.
- ◆ Study methods, such as study design and duration, as well as items that will be used to assess the risk of bias, such as sequence generation, allocation concealment, and blinding.
- ◆ Data regarding participants (e.g. sex, age, ethnicity, and education level) and setting (e.g. institution and geographic location) which may influence the size of the effect estimate or assist in assessing the applicability of results.
- ◆ The number of intervention groups and the details of the specific interventions involved. Any information relating to the fidelity with which the intervention was administered (i.e. the extent to which it was implemented as planned) should be obtained.

This is particularly important in preventive or complex interventions, which are usually implemented under 'real-world' conditions.

- ◆ Information regarding the outcomes such as their definitions, time points at which they were measured, and units of measurement should be collected. Usually, this is done only for those outcomes pre-specified in the review protocol. However, listing all other outcomes reported in the included study may enable analysis of risk of bias due to selective outcome reporting.
- ◆ Results should be collected only for those outcomes pre-specified in the protocol. For a meta-analysis it is also necessary to collect the data for analysis (see next section on data extraction).
- ◆ Other information to be collected could include funding source, details of ethics approval, name of contact of authors, citations, etc.

Once the data to be collected have been identified, it is necessary to design appropriate data collection forms. These may be electronic or paper-based, depending on the preference of reviewers. Paper-based forms allow extraction of data anywhere, and they are easier to create and use, whereas electronic forms offer the advantages of data extraction and entry in one step, programming of forms, and better storage, sorting, and retrieval of data in reviews with large number of studies (Higgins and Deeks 2011). Usually several forms, serving different purposes, are used.

Data extraction

Data extraction refers to the process of recording all the relevant data from the included studies onto data collection forms. Piloting data collection forms using a representative sample of studies is recommended. This will help to identify data that may not initially have been considered for collection, and to detect coding that might be unclear (Higgins and Deeks 2011).

To reduce the risk of errors during data extraction, it is advisable that at least two reviewers, working independently, are involved in extracting the data. Any disagreements between the reviewers should be resolved through consensus or arbitration by a third person. Blinding data extractors to study details, such as names of authors and results, may decrease the risk of bias (Jadad et al.

1996). However, as the evidence for this practice is not conclusive (Berlin 1997), routine blinding of data extractors is not currently recommended.

It is important to keep in mind that a single study may have been reported in more than one paper. Reviewers should be vigilant to the existence of the often covert practice of reporting the same data in different journals or even in the same journal at different times (Von Elm et al. 2004). The inclusion of duplicate publications with repeated observations in a systematic review will introduce bias on account of undue weight given to the findings concerned (Tramer et al. 1997). Where multiple papers arising from the same study report different data, it is, however, necessary to include all relevant articles in order to ensure that data extraction is complete.

The type of summary data needed for subsequent meta-analysis will vary according to the type of outcome involved. For dichotomous outcomes, the numbers of participants who did and did not experience the outcome in each intervention group should be extracted. In the case of continuous outcomes, the mean and standard deviation, as well as the number of participants in each group, will be needed.

Where the desired summary measures are not reported, they may be derived from other statistics. For example, numbers of participants may be derived from percentages or effect estimates, such as odds ratios. Sometimes study authors will have to be contacted for clarification.

Assessing risk of bias

Once the data extraction is completed, each study should be carefully assessed for the risk of bias in the design, conduct, analysis, or reporting of a study. The main aim of this exercise is to guide interpretation of the findings of the review. In extreme cases, one may choose to exclude a study which is so fundamentally flawed that its results are not valid.

There are several methods for assessing the risk of bias. The Cochrane Collaboration recommend a 'domain-based evaluation' for clinical trials in which judgements are made about the risk of bias in each of the following domains: selection bias, performance bias, detection bias, attrition bias, reporting bias, and other bias (Table 5.15.2).

Table 5.15.2 Domain-based scheme for classification of bias in included studies

Type of bias	Description	Relevant domains
Selection bias	Systematic differences in the baseline characteristics of the groups that are compared	<ul style="list-style-type: none"> • Sequence generation • Allocation concealment
Performance bias	Systematic differences between groups in the care that is provided, or in exposure to factors other than the interventions of interest	<ul style="list-style-type: none"> • Blinding of participants, personnel and outcome assessors • Other potential threats to validity
Attrition bias	Systematic differences between groups in withdrawals from study	<ul style="list-style-type: none"> • Incomplete outcome data • Blinding of participants, personnel and outcome assessors
Detection bias	Systematic difference between groups in how outcomes are determined	<ul style="list-style-type: none"> • Blinding of participants, personnel and outcome assessors • Other potential threats to validity
Reporting bias	Systematic differences between reported and unreported findings	<ul style="list-style-type: none"> • Selective outcome reporting

A judgement relating to the risk of bias for each item is assigned, which is supported by a description of what was done in the study. The judgement is indicated by answering a pre-specified question (e.g. 'Was the allocation sequence adequately generated?') which requires a 'yes' representing a low risk of bias, 'no', a high risk of bias, and 'unclear' an unclear or unknown risk of bias. Criteria for judging the risk of bias are provided in The Cochrane Collaboration's 'risk of bias tool'. The final step involves the risk of bias assessments being summarized across all domains for each study, and across all studies by indicating the proportion of domains studies with low, unclear, or high risk of bias.

Risk of bias is assessed based on the information in the reports of trials. Sometimes, the reported information may be insufficient to make critical judgements about the methods of a study. In these cases, it is important to contact the study authors to clarify any issues regarding study design or missing data that are not described clearly in the report (Mullan et al. 2009; Higgins et al. 2011).

Summarizing the evidence

One of the reasons for conducting a systematic review is that the individual studies are too small to provide a reliable and robust answer on their own. The review seeks to bring together the studies of relevance to the question in order to avoid undue emphasis on the findings of any single study, to minimize bias and to maximize statistical power by combining all the relevant data if this would be appropriate. This will help to overcome the biases of focusing on the findings of individual studies, and the effects of chance that may lead to an over- or underestimate of the true effect. Even when a randomized trial is well conducted and has minimized the possibility of biases that might overwhelm any true difference between the interventions being compared in that study, it is still susceptible to the effects of chance and the mathematical testing that is done to assess this cannot provide certainty on whether or not the result was distorted by chance, or on the size or direction of any distortion. However, combining the data from multiple studies in a meta-analysis will serve to minimize the effects of chance, such that any over- or underestimate is likely to be smaller than that in a single study. Even when the mathematical combination of the results of studies is not done, presenting them all in the same place and in the same way helps the reader to compare and contrast the studies in the review.

This provision of a summary of the evidence helps the systematic review fulfil the purpose of placing existing research in context, ensuring that new research is designed and implemented in the most appropriate way. And, when systematic reviews are used as part of the presentation of the findings of a new study, it ensures that those findings are seen in proper context (Clarke et al. 2010).

In deciding on how to summarize the evidence identified for the review, the reviewer might use a quantitative approach seeking to combine the results in a meta-analysis, a qualitative approach in which each study's findings are kept separate, or both. The choice about these techniques depends to some extent on the heterogeneity in the outcomes measured across the studies, since if there is too much variation in the outcomes that were measured, the measurement tools that were used, how or when they were used, or in how the results are made available, it might be impossible to combine the data. Efforts are underway in many areas of healthcare to help

overcome this by reaching consensus on standardized core outcome sets, and the COMET Initiative is bringing such examples together and facilitating the development of further core outcome sets (Williamson et al. 2012), but the challenges in the existing literature can be substantial. These challenges, which might prevent the combining of data in the review, can also make it much more difficult to compare and contrast the included studies.

Regardless of whether they will do a meta-analysis, reviewers need to decide how much or how little information to extract and report for each study, and the sources to be used, especially if published reports are inadequate (Clarke and Stewart 1994). In compiling as complete a dataset as feasible and sensible, the principles of minimizing systematic biases and chance effects must be applied. If a meta-analysis is to be done, compatible data should be sought for all relevant trials and, if these data are not available, the proportion of missing data needs to be small enough to allow the reviewer and the reader to feel confident that the review's findings are robust. In particular, the reviewers need to consider whether the unavailability of the data is due to results-related bias. If it is, the meta-analysis of available data will itself be biased, leading to potentially misleading overall findings and conclusions.

There are several benefits of doing a meta-analysis if it is appropriate so to do. It provides a more precise estimate of the treatment effect, helping one to be more confident about the size of any effect. There is more statistical power to detect small effects, which may be clinically significant; and it helps in the evaluation of the applicability of the results to other settings. However, one of the important decisions that a reviewer has to take is whether the trials are similar enough that averaging their results is meaningful. This is done by considering whether there is excessive heterogeneity in the design of the studies (including the interventions and participants studied). Statistical tests are also available to assess whether the results of a series of trials might differ from each other by more than chance (Higgins et al. 2003).

In seeking data and other information from the original researchers to prepare their summary, the reviewers might try to gather aggregate data, for example, by asking the original researchers to complete a table; or they might seek data at a finer level, such as that for individual participants. This gathering of data from the original researchers might make the dataset available for the review more complete, up to date, and accurate than anything that was previously available. It also helps the review to perform standardized analyses across the studies (Stewart et al. 1995).

A variety of techniques for combining results from separate studies in a meta-analysis is available to the reviewer (Cooper and Rosenthal 1980; Deeks 2002). The overriding principle of most of these is that each study is analysed separately and the overall result for the review comes from combining these results from the individual statistics. In this two-step approach, participants in one study are only directly compared with others in the same study and it is now fairly standard for the results of these analyses to be shown as a forest plot (e.g. Fig. 5.15.1). This allows the reader to see the contribution of each study (Lewis and Clarke 2001; Glasziou and Sanders 2002; Higgins et al. 2003).

In planning and conducting the statistical analyses for any review, careful consideration needs to be given to the types of analyses, the options available for these analyses, and the reliability of the overall average. Once again, the effects of chance and

bias should be considered carefully. This is for the overall results and for any subgroup analyses that are conducted; especially if decisions about the analyses to conduct and present are due to fore-knowledge of the likely findings (Counsell et al. 1994). This can be a particular problem for systematic reviews, since they are retrospective research and some or all of the findings of the included studies might already be known to the reviewers before they reach the stage of planning or conducting the analyses.

Subgroup analyses present the reviewer with the dilemma that having brought together the data from multiple studies, they might now wish to break it apart again into subgroups to explore the effects in different patients or settings, or when different interventions were used. This needs to be done with caution because of the possibility that spurious, chance results will be obtained; which will be misinterpreted as being of importance in making decisions about healthcare (Counsell et al. 1994; Clarke and Halsey 2001; Bender et al. 2008). Even if there is an *a priori* reason to expect a subgroup analysis to show something different to the overall result, this is no guarantee that a statistically significant difference is reliable clinically. This is because the more analyses are done, the more likely it is that statistically significant results will be found, even when there is truly no difference between the subgroups. Subgroup analyses in a systematic review should be regarded as a way of showing that the direction of effect is the same across different types of patient or as a generator of a hypothesis for testing in future research. Regardless of whether subgroup analyses are done, it is often more reliable to assume that the overall result is as good, and if not a better, estimate of the relative effects of treatments in the particular type of patient than that obtained by looking at the results for just these types of patient in the review. This is because the effect of chance will be smaller for the overall result than it would be on the result in any subgroup.

Systematic reviews might also include sensitivity analyses, which ideally should also be planned in advance. A sensitivity analysis is used to determine how sensitive the results of the systematic review are to the decisions that the reviewer took about how the review was done. They are particularly useful where there is uncertainty about the choices that a reviewer needs to make. For example, sensitivity analyses could be used to determine the effect of including studies published in languages other than English, of using data from studies assessed to be of poor quality, or of choosing one statistical technique over another.

The multiplicity which might arise in a systematic review because of the variety of outcomes, and measures of these outcomes, available is compounded further by the variety of ways to analyse these in order to obtain an estimate of the difference between the intervention and the comparator. If a meta-analysis is done, this multiplicity will arise at the level of the overall estimate of effect. If the results of each study are kept separate, with no combination of these in a meta-analysis, it arises at the study level. Typical effect measures in systematic reviews that use dichotomous, or binary, data are estimates of risk (either a ratio or absolute difference) and odds (almost always a ratio).

The decision on which effect measure to use should, ideally, be taken when the systematic review is being planned. It should be based on the mathematical appropriateness of the effect measure for the type of data to be analysed. As with any of the decisions when conducting a systematic review, changes to this *a priori* plan should be kept to a minimum, and should be documented

and reported. Any changes that are made because of the reviewers' preference for one result over another need to be treated with particular caution, because of the risk of bias. In meta-analyses of dichotomous data, it is most common for the odds ratio, risk ratio, or both to be used (Deeks and Altman 2001).

In some cases, the original intention for the effect measure will turn out to be mathematically inappropriate or suboptimal because of the nature of the data identified for inclusion in the review. This should be dealt with and described in a transparent way by the reviewers. They should avoid conducting multiple exploratory analyses using different effect measures and then focusing on the analysis that generates their preferred result. In circumstances where a variety of effects measures are appropriate, the different analyses may be conducted, and all that are conducted should be reported. The greatest confidence in the findings of the review would then arise if there is consistency among the results from the different effect measures. If the results differ in important ways, the reviewers and the users of the review need to be cautious.

If the meta-analysis uses continuous data, the typical effect measure will be the mean difference. If the data from the included studies relate to the same outcome but they were measured in different ways, for example, by using a variety of scales to measure satisfaction with the provision of care, this needs to be standardized. The reviewers might also have the option of dividing the continuous data into 'high' and 'low' in order to dichotomize the outcome and, thereby, use effect measures such as the risk ratio or odds ratio. Particular caution is needed in such circumstances, especially if there is no natural or well-accepted threshold for this splitting of the data.

Writing up the review

In recent years, there has been increasing recognition of the value of guidelines on the reporting of a wide variety of types of research study, including randomized trials (Schulz et al. 2010), observational research (von Elm et al. 2007), and studies of diagnostic test accuracy (Bossuyt et al. 2003). The principal guide for the reporting of systematic reviews is PRISMA (Moher et al. 2009), which updated the QUOROM statement (Moher et al. 1999).

This section of this chapter outlines some of the key elements in the reporting of a review, which should help both with the preparation of the report and with its use. When preparing a report of a systematic review, though, it is important to bear in mind what the reader will be looking for. The traditional format of scientific papers of Introduction, Methods, Results, and Discussion is used in the following, but the reports of some reviews might change this order, or move some content to appendices or supplementary papers, depending on the interests and needs of their readers.

Title for the review

The title might flow naturally from the question for the review, containing elements relating to the population being studied, interventions or actions, the outcome of most interest, the study designs incorporated into the review, and the fact that the research being reported is a systematic review. The title should help the reader to decide whether the review is potentially relevant to them and might be particularly important in ensuring that the review is retrieved by people searching for research in the particular

area. Some titles might be declarative, very briefly summarizing the main finding of their review, but this might not be possible in reviews covering more than one intervention, population, or outcome, where there are multiple important findings.

Question and purpose for the review

One of the distinguishing features of systematic reviews over more traditional reviews is the use of a clear research question at the design stage of the review. Formulating and clarifying the question at the outset of the review and at the start of its report is important for the reviewer, and then for the reader. The question will also help to reveal the purpose of the review, which might have been to provide evidence to guide future practice, or to map out existing research to help design a new, definitive study. For example, the question might be ‘What are the effects of an incentive scheme to encourage exercise in the adult population?’, or ‘What types of incentive scheme to encourage exercise in the adult population have been tested in trials?’, or ‘How have trials of incentive schemes to encourage exercise in the adult population been assessed?’.

A systematic review might contain more than one question and comparison, and this should also be made clear early in the report. For example, the review might cover the comparison of an intervention with usual care, comparisons of different forms of the intervention, or comparisons (direct or indirect) between the intervention and alternative strategies.

Background

Setting the scene for the review will help orientate the reader to the topic and is also an opportunity to explain the importance and relevance of the review. The Background section might provide details on how common the circumstances or condition under investigation are; how the intervention was developed, how it might work and how common it is in practice; and any relevant studies that are already likely to be well known. Information on the consequences and severity of the outcomes being assessed might be helpful. It might also be important to set out the reasons for conducting the review in a particular way, especially if there are alternatives that might be in the minds of the reader. If the review had a pre-prepared protocol or was prospectively registered, this could also be stated in the background section.

Inclusion and exclusion criteria

In providing the eligibility criteria for a review, it may be important to be clear that these are what the reviewers sought, which will not necessarily be matched completely by what they found and were able to include in the review. For example, the review might have looked for a variety of interventions to protect factory workers from noise but found that only a few of the commonly used strategies had been tested in research (Verbeek et al. 2012). For most reviews, the eligibility criteria can be set out under domains, as discussed earlier in the chapter in relation to the use of PICO. This would identify the types of participants, interventions, actions or strategies, outcome measures, and types of study design.

The types of participants should include information on the types of people that would be eligible. This might contain information about personal characteristics such as sex, age, socioeconomic group, and diagnosis, as well as information about their

setting. The types of interventions, actions, and strategies covers what was to happen to the participants, and needs to contain information on any interventions, actions, and strategies that were used for comparative purposes. Types of outcome measures might be divided into primary and secondary outcome measures. It may also be helpful to distinguish ‘outcomes’ (e.g. depression) from ‘outcome measures’ (e.g. the instrument used to measure depression and the timing and application of the instrument). If there is a core outcome set relevant to the circumstance of the review, this might be referred to in this section (Williamson et al. 2012). Finally, the types of studies sets out which research designs were eligible for review.

Within the eligibility criteria, providing both inclusion and exclusion criteria can help clarify what would definitely be eligible for the review, and what would not be. This should not simply include ‘mirror images’ of the inclusion criteria in the exclusion criteria. For example, if the inclusion criteria require that people were living in residential care homes, it is superfluous to mention the exclusion of people who live in other settings. Rather, the exclusion criteria might be used to note that a subpopulation of people who would otherwise be eligible are not eligible, such as people in the care homes who are under the age of 60 years.

Methods

The authors of the review should describe what they had intended to do, and what they were able to do given the material that they found for their review. If they had a protocol for the review, this could be referred to here. As a minimum, the Methods section should provide details of the search strategy, how eligibility was determined, methods for data extraction or collection, and the techniques used to summarize the findings, which—as discussed earlier—might be quantitative, qualitative or both. Strategies used within the review to minimize bias, such as blinding during data extraction, checking of reference lists and obtaining unpublished data, and to minimize error, such as independent assessment for eligibility should be described. Changes to the methods between the original plans or the protocol for the review, and the final review should be noted and explained.

Results

The Results section might begin with details of what was found for the review, separating studies that had been judged to be eligible, ineligible, and eligible but ongoing (with results not available). This might include the PRISMA flow diagram to show the attrition at each stage in the process from original search to final inclusion in the review’s analyses. Details should be provided on each included study, which might vary in depth from a thorough description of several features of each study, to a brief summary and details of sources of more information, such as the citation for a published report, link to a study website or to the entry for the study in a research register.

Studies that were judged eligible but were excluded, and studies which readers might expect to have been included but weren’t, should be reported along with a reason for their exclusion. This reassures the reader that these studies were identified by the reviewers. Failure to mention them might raise concerns in the reader’s mind about, for example, the robustness of the searches for the review or the potential for reporting bias.

Whether or not the review includes quantitative or qualitative synthesis of the included studies, if the reviewer presents sufficient detail for each study and its findings, this would allow the reader to repeat such syntheses for themselves, perhaps changing how the studies are grouped or leaving out some studies. The use of forest plots for each meta-analysis is a fairly straightforward way to both show the proportional contribution of each study and present its numerical results (Lewis and Clarke 2001).

Conclusions

The next section in this chapter goes into more detail on the interpretation of the findings of a systematic review but some of the things for the reviewers to consider in their Discussion section are outlined here. They need to be cautious about introducing new evidence at this point to answer the question if, for example, there was insufficient information available in the studies included in the review. Having been so careful in planning the systematic review itself, it may be undermined by non-systematic approaches to introducing alternative sources of evidence for the review's primary question in the Conclusion section. Where relevant, the reviewers' conclusions might be separated into their opinions on the implications of their review for practice and for further research. The latter might include specific suggestions on the types of study that are needed now, given the existing research that has been summarized in the review (Brown et al. 2006; Clarke et al. 2007).

In a complex or large review of the effects of interventions, the reviewers might choose to summarize their conclusions by highlighting where they have found convincing evidence of which interventions are beneficial, harmful, are lacking in evidence and need more research, or are lacking in evidence from the studies in their review but which probably do not warrant more research. If the review is not about interventions but concerns, for example, the relationship between characteristics of people and their behaviour, a similar categorization of the conclusions on the basis of confidence about a positive or negative relationship, one that is unproven and worthy of more research, and one that is unproven but does not justify more research, might be helpful. This categorization of the interventions might help policymakers to focus in on those that might be introduced or reinforced, abandoned (Garner et al. 2013), or restricted to use in research.

Interpreting the findings

When interpreting the findings of a review, either as the person preparing the review or someone reading it, it is important to remember some of the key principles underpinning evidence-based healthcare (Sackett et al. 1997). The systematic review is a source for one part of the evidence needed for well-informed decision-making. In the context of systematic reviews of the effects of interventions, this will be an estimate of the difference between the alternative interventions. In the context of, for example, associations between the presence of a characteristic, such as social deprivation, and an outcome, such as diabetes, it will be the estimate of the strength of this association. Other types of evidence are also needed to make a well-informed decision, including information on diagnosis, expertise, feasibility, values, and preferences. Some of this evidence might be provided

by additional systematic reviews of other types of research, which could be incorporated into the main review, but some will come from the target population to whom the review will be applied. This makes it important for the review to provide the information needed to use its findings in practice and to interpret the findings and recommendations cautiously.

One way to decide on the potential relevance of the review to settings other than those in the included studies, is to consider whether there are any strong reasons why the participants in the studies included in the review, the interventions assessed in these studies, and the outcome measures reported are not sufficiently similar to the people, interventions, and outcome measures of relevance in other circumstances and the values and preferences of the population for whom the results will be applied.

Some examples of the decisions that might need to be made about the possible applicability of the findings of the review are if the evidence in the review is from research done in academic research hospitals in large cities but it will be used in decisions for clinics in rural settings; the trials were done in North America and the burden of the problem is greatest in Africa; or the patients in the trials were from a particular, high socioeconomic group but the findings will need to be applied to other groups.

Earlier in this chapter, the challenges of subgroup analyses were noted and one possibility for applying the results of a heterogeneous review to a target population is to consider the results within the target population subgroup. As noted, this needs to be done with caution because of the problems of lessening statistical power, multiplicity, and bias. In fact, the more reliable guide to the effects for a patient in the subgroup of interest might be the overall average from the meta-analysis, rather than the specific result from the subgroup analysis. One way to assess this and to decide between the overall result and the result of a specific subgroup is to consider whether the rationale for the subgroup analysis is to identify different effects among the subgroups or to identify similarities. For instance, do the subgroup analyses provide reassurance that the difference between the treatments is similar regardless of specific patient characteristics (such as age, setting, or socioeconomic group)? Or, do they show that one intervention will be beneficial in one type of patient but harmful in another? This might happen if a treatment has a beneficial effect for one outcome but increases the risk for another. The treatment might be regarded as beneficial, on average, for people with few risk factors for the latter; but harmful in those at high risk of it.

As well as considering whether or not there are substantial differences between the participants in the studies in the review and people for whom it will be applied, it is also important to consider whether the interventions in the review are similar enough to the ones that would be used in practice. This might be straightforward if the interventions were drugs that can be administered in a standard way but it might be more difficult for interventions that are more skill based, such as surgery or psychotherapy; or for complex interventions, such as a community intervention strategy to reduce criminal behaviour or a training programme for nurses. An additional challenge here is that information on how the drug should be administered might be well described in the included studies and the review, while the details on a complex intervention might be inadequate for implementation.

Assessing the quality of a systematic review

There are a number of guides to help readers assess the quality of systematic reviews (Katrak et al. 2004). Three of the commonest ways to assess the quality of systematic reviews are tools based on the Overview Quality Assessment Questionnaire (OQAQ) developed by Andy Oxman and Gordon Guyatt (1991), the PRISMA checklist (Liberati et al. 2009; Moher et al. 2009), and the AMSTAR tool (Shea et al. 2007, 2009). As part of the appraisal of the systematic review and when deciding upon its relevance to a health or social care decision, the user should also consider whether the review is sufficiently up to date. To be truly up to date, a systematic review would need to have been completed just before its findings were to be used and would need to include all the relevant research available at that time. This is not practical. It would require reviews to be revised as soon as new evidence became available. Although this might be possible if updating the findings of a systematic review simply involved the insertion of data from the latest evidence into a meta-analysis, the separate chapter on systematic reviews shows that the review process is more complex than the statistical combination of the results of the included studies. Reviewers need to apply their eligibility criteria, appraise the quality of the studies, make decisions about the suitability of the outcome data, and draw conclusions about their findings. This will take time. It also needs to be preceded by searching for studies and the assessment of the retrieved records for potential relevance. In considering how up to date a review is, it is also important to consider whether the review is so early in the evaluation of an intervention that the availability of studies for it was influenced by time-lag bias (Hopewell et al. 2007b), meaning that the conclusions are likely to change as this bias is corrected by increased availability of studies with less favourable findings.

Updating systematic reviews

Unless reviews are regarded as historical documents summarizing the evidence up to the time point of the review, reviewers and commissioners of reviews need to consider how the review might be kept up to date, so that it remains a valid source of knowledge for decision-makers in the future. For example, the intention for Cochrane Reviews is that these will be updated periodically and, at least, every 2 years or annotated to explain why this has not been done. The ideal, of course, might be that a review includes all relevant research available at the time that it is being used to inform a decision but this is not practical without a process for new evidence to be continually incorporated into existing reviews. The updating process takes time and can also serve to maintain the contemporary relevance of the review. This may be especially important if the review uses information that changes over time, such as economic costs, the organizational structures for delivering healthcare or the processes in which decisions are made about healthcare.

Statistical methods

Gail Williams

Introduction to statistical methods

Statistics is the study of mathematically based techniques used to collect, analyse, and interpret quantitative data. In public health, this occurs in a complex of biological, clinical, epidemiological, social, ecological, and administrative systems. Sometimes we want to describe, explore, or summarize data without extending our findings beyond the coverage of the data we have—that is, the sample. More usually, however, we want to extend, or generalize, our findings from the sample to a larger group, sometimes called the ‘target’ population. In this situation, we need to consider carefully two aspects of our data collection. Firstly, what was the actual source of our data, and how did we select the sample from the population? If we deliberately excluded some people in our sampling, or made it more difficult for some rather than others to be included in our sample, then the sample may not represent the population equitably—we may have a *biased* sample. Secondly, we expect that if we repeat the data collection, even under identical conditions, we will get somewhat different results. This variability, called *sampling variability*, needs to be taken into account in deciding how precisely findings from our sample reflect what is happening in the population.

We now have access to a wider range of statistical techniques than ever before. It is important that analytical methods used are appropriate to the sampling strategy, the type of data collected, and the research questions to be answered. We usually want to generalize our results to a population. The process of using samples to draw conclusions about populations is called *statistical inference*.

In this chapter, I discuss basic concepts underpinning data analysis and statistical inference. The ideas of probability theory are heavily involved in random sampling, which takes place under the assumption that a probability model governs the selection of the sample. Probability models are also involved in helping quantify uncertainty in sample estimates. I will also discuss a range of statistical techniques in common usage, outlining the underlying assumptions, and focusing on interpretation.

Basic concepts

Populations, samples, and sampling

For the purpose of discussing statistical methods, a *population* is the complete set of entities we want to consider in our enquiry. The entities may, for example, be free-living humans, hospital patients, disease vectors, communities, or health services. A *sample* is defined generally as a subset of a population. The sample may not

be of interest in itself; its use is to provide information about the population, such as to estimate the incidence of malaria or to compare the risk of lung cancer among smokers and non-smokers. By taking a sample from the population instead of enumerating the entire population, we save resources and time. We may choose to spend some of these savings on achieving greater quality of measurement, or better follow-up of those we select. The price paid, however, is that we cannot make an absolute statement about the population; we have only an estimate—the sample incidence, or the excess of lung cancer in our sample of smokers.

Probability and random sampling

The solution to the concerns of obtaining an unbiased estimate and being able to quantify uncertainty entails the notion of ‘fairness’ in the sample selection process. A ‘fair’ method of sampling does not favour or discriminate against any member of the population. However, if we can quantify any ‘unfairness’, we can correct for this in the analysis, and so still obtain an unbiased estimate. For example, if males are twice as likely as females to be selected from a population that contains equal numbers of each sex, we can compile the data so that females have twice the weight. Thus, what actually matters is that we know how likely it is that each individual in a population is selected for the sample—i.e. the *probability of selection* of each person.

We measure probability with a single number, which has particular properties, some of which are as follows:

- ◆ Probabilities lie between 0 and 1 (or 0 and 100 per cent).
- ◆ If the probability of the event is 0, there is no chance of the event occurring.
- ◆ If the probability of the event is 1, the event is certain to occur.
- ◆ The combined probability of a complete collection of events is 1.

A process whose outcome is unpredictable and governed by rules of probability is termed *random*. If we are drawing random lots to select one person from 100 people, we can say (before sampling) that the probability of inclusion of an individual is 1 in 100, but we cannot predict exactly which individuals will be included. Other classic random processes are outcomes of coin tosses or rolls of a die. We know that in the long run, the chance or probability of a head is 0.5 or 50 per cent on any one toss of an unbiased coin, but the outcome of any particular toss is unpredictable.

The word ‘random’ as used in statistics has a specialized meaning. It is used to describe a process whose outcome (in this case, getting selected for the sample or not) is governed by the play of chance. Random does not mean ‘haphazard’ or ‘arbitrary’.

A sample in which each person in the population has the same chance of selection is called a *simple random sample*. This can be achieved by listing all the members of the population (this list is called a *sampling frame*), applying an unbiased random process of selection, such as drawing lots or using computer-generated random numbers, and obtaining a sample of the required size. In practice, compiling a sampling frame can be difficult. More generally, a sample for which we know the probability of selection (whether the same or not) for each person in the population is called a *probability* or *random sample*.

Recommended sampling techniques usually require identifying a population as the source of our sample. Thus, to obtain a sample of 7-year-old children to estimate the prevalence of childhood asthma, we might begin by obtaining school class lists. It is important to be clear about the population for which we want to draw conclusions. Is it the population of 7-year-old school children or is it all 7-year-olds? It may only be feasible to sample formally a restricted population (school children), but we really want to make conclusions about a wider population (all school-aged children). This wider population is sometimes referred to as the *target population*. Whether conclusions can be extrapolated to a wider population than actually sampled is then a matter of judgement.

If someone has no chance of being selected in the sample, and they are different with respect to the characteristics we are measuring, or if individuals vary in both their chances of selection and the characteristics of interest, we expect to have a biased sample. We often have no way of predicting how individuals vary in the characteristics being measured, but if we can control, and therefore know, the probability of selection, we can control the potential for bias. Sampling which does not follow these rules is termed *non-probability sampling*. Here we do not know the probability of inclusion of population units. Sometimes we cannot define the population sampled. These methods include convenience samples (people waiting in outpatient departments) or haphazard samples ('people in the street').

Critically, a sample is termed a random sample because of its method of selection. We cannot determine whether a sample is random by examining it, we must know the process by which it was obtained. Examining a sample for observations which are deviant in some respect or comparing its characteristics with those of a target population cannot ascertain randomness.

Thus, 'random' does not equal 'representative' (although using a random method of selection, in some sense, decreases our chances of non-representativeness). In summary, the reasons for using random sampling are to:

- ◆ Enable quantification of the sampling variation using probability theory.
- ◆ Ensure that a statistically unbiased estimator of the quantity of interest is obtained.

Complex sampling

Complex sampling is the term used to describe probability sampling which is not simple. A variety of methods, or their combination, may be used. *Stratified sampling* is used when the population consists of a number of subpopulations or strata which vary in the quantity of interest. We sample randomly within each strata separately, in order to control the stratum-specific numbers, or to take into account large variability across strata. For example,

typically (but not universally) urban areas have larger populations than rural areas. For sampling such a population we might first wish to stratify by rural/urban status, to achieve predetermined numbers or sampling fractions in each region. If sampling fractions differ for each stratum, the overall sample will not be a simple random sample, because the probability of selection will vary across strata; it will, however, be a probability or random sample because we can, knowing the sampling fractions within strata, calculate the probability of selection of any unit. If we control the stratum sizes to exactly reflect those in the population we can achieve greater precision than a method which ignores strata. In designing a stratified sampling scheme, we need to be clear about our priorities—do we want to disproportionately increase the numbers in a particular stratum, or do we want to control optimally for interstrata variability?

If we select a simple random sample from a large city, individuals selected would be widely scattered and costly to reach if we have to conduct face-to-face interviews, for example. *Cluster sampling* involves selecting groups of individuals, rather than individuals themselves, to increase logistical efficiency. A random sample of people in a city could be achieved by first selecting a simple random sample of census collection districts, and including all people living within the selected districts. The disadvantage is that the sample may be artificially 'homogeneous'; the selected people may be more alike than if we had used a simple random sample. This statistical inefficiency is measured by what is known as the *design effect*, which must be estimated in the analysis phase.

Two-stage sampling is similar to cluster sampling except that a sample of the cluster is taken instead of the whole cluster. This helps overcome the problem of 'homogeneity' to some extent, but creates a more complex process, as there are two sampling stages.

In some cases, the sampling fractions for selecting clusters and selecting from them are carefully manipulated so that the overall probability of each population unit being selected is the same. One such method is called *sampling proportional to size*—clusters are selected with a probability proportional to their size (larger clusters have larger chance of selection) and then a fixed number of individuals is selected randomly from each selected cluster. Another method is *proportional sampling* in which clusters are selected with equal probability, and a fixed sampling fraction is used to select individuals from each selected cluster. Cluster sampling and two-stage sampling do not require an explicit sampling frame for the whole population. In two-stage sampling we need a list of first-stage units (e.g. census districts) and then a list within only each first-stage unit actually selected. This is an advantage, particularly if sampling poorly documented populations. Two-stage sampling can be extended to three or more stages, for example, districts, towns, households, and individuals.

Stratified, cluster, or multistage sampling strategies provide opportunities to measure entities at all levels. Thus, factors may be relevant at the village level (presence of a health centre, degree of remoteness), the household level (family income, access to piped water), or the individual level (age, sex).

Complex sampling allows individuals to have different probabilities of inclusion in a sample. It is imperative that we can calculate each person's probability of inclusion, otherwise we cannot make the necessary analytical adjustments. All information relevant to probability of inclusion must be documented in the course of the sample selection.

Complex sampling schemes require expertise and care to design and analyse. It is usually necessary to seek advice from a professional statistician. Most statistical software has appropriate analytical procedures, and these may have particular requirements in the construction of the data set.

I next consider the issue of characterizing information collected on our sample. This involves categorizations of variable types, crucial in deciding how to present or analyse data.

Describing variables

A primary distinction is made between *quantitative* and *categorical* variables, because these are analysed using different techniques. The distinction is based on the kinds of *values* a variable may take. For the purpose of statistical analysis, what matters is the type of measurement of the variables, specifically whether they are measured on a numerical scale (such as age) or in categories (male or female). Sometimes a numerical variable (e.g. blood pressure in mmHg), is subsequently categorized (hypertensive or not hypertensive), but it is important to realize that it is the final form (numerical or categorical) of the variable that matters for analysis.

Categorical variables

A categorical variable is one whose values are expressed in mutually exclusive categories (e.g. survival status, social class, sex, religion, extent of disability). These are further subdivided into *nominal* and *ordinal*. A nominal variable has values that are categories, with no implicit ordering of the categories (e.g. sex, religion). A variable with two levels only (e.g. sex) is referred to as a

binary, or *dichotomous* variable. Categories of an *ordinal* variable have an underlying order (e.g. social class, extent of disability). Categorical variables are usually described by *frequencies* and *percentages* in each value category, and presented in tabular or graphical form, such as bar charts or pie charts. For example, a study of child mortality examined the types of birth attendant at delivery of children in the study. This can be presented in a table (Table 5.16.1), or graphically in various ways (Fig. 5.16.1).

Table 5.16.1 Community-based sample of children under 5 years of age in Bohol Province, the Philippines, 1984–1986, by birth attendant at delivery

Birth attendant	Number of deliveries (n = 511)	Percentage of deliveries (%)
Untrained TBA	8	1.6
Trained TBA	224	43.8
Midwife	186	36.4
Nurse	3	0.6
Physician	34	6.7
Unknown	56	11.0
Total	511	100.0

TBA, traditional birth attendant.

Source: data from *Acute Respiratory Infection Research Project*, funded by the Australian International Development Assistance Bureau, Bohol, Philippines, Copyright © 1986–1992.

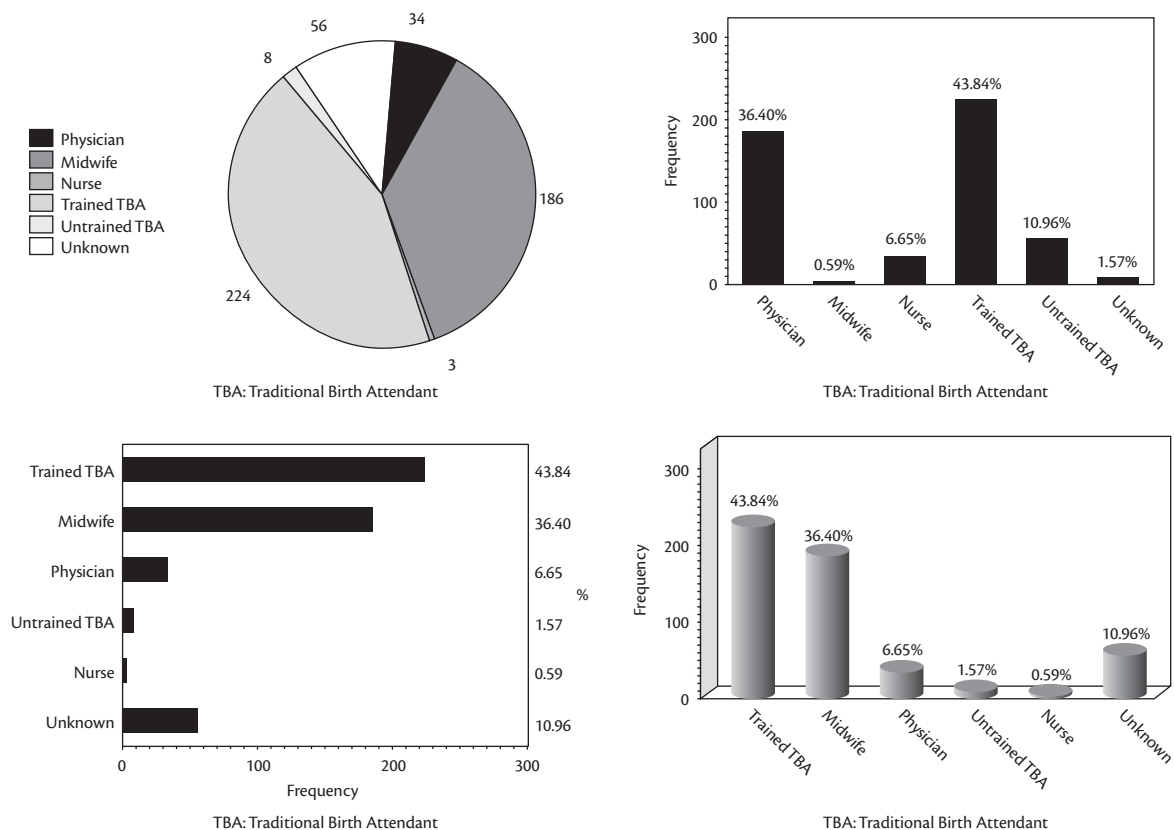

Fig. 5.16.1 Community-based sample of children under 5 years of age in Bohol Province, the Philippines, in 1984–86, by birth attendant at delivery. Alternative graphical methods of presentation.

Although the choice of graphical presentation is partly a matter of taste, bar charts tend to be used for ordinal variables (as the bars can be ordered appropriately) and pie charts used for nominal variables (to de-emphasize order).

Quantitative variables

Quantitative variables express values in numerical measurement (e.g. height, age, number of births), and are further subdivided into *discrete* and *continuous* variables. A discrete variable takes only certain distinct values, usually whole numbers (e.g. number of births). A continuous variable take all values within the observable range (e.g. age, birthweight, serum cholesterol). It is essential to specify units of measurement.

Frequency distributions

Quantitative variables are usually described, at least initially, in a frequency distribution, which tabulates, in mutually exclusive and contiguous groups, the number or percentage in each group. For example, a study documents birthweights (kg) of children born at a major obstetric hospital in Brisbane, Australia, using a sample of 500 full-term babies (gestation of at least 39 weeks). A frequency distribution portrays this (Table 5.16.2), after cut-off points for groups of birthweight are chosen.

Choice of cut-off points for groups is to some extent arbitrary. We usually want at least eight groups, and prefer them to be evenly spaced, although this is not strictly necessary. Some recommend using \sqrt{N} (square root of N) groups, where N is the sample size. We may use cut-offs defined for other purposes (e.g. using 2.5 kg as a cut-off identifies ‘low’ birthweight babies, as commonly defined). If we want to compare with a frequency distribution from another study, we use the same cut-off points. A frequency distribution is often graphed in a histogram (Fig. 5.16.2A). This usually requires a

large number of values to provide a picture of the shape of the distribution, which may be important when we are choosing a method of analysis. Not all distributions are symmetric. A variable may have a negatively (Fig. 5.16.2B) or positively (Fig. 5.16.2C) skewed distribution, when the peak is pushed to the right or left, respectively.

Measures of location

The measure most commonly used to summarize the magnitude of a quantitative variable is the *mean* (the usual arithmetic mean, or average). When some values need to be given more or less weight, a *weighted* mean may be used. When distributions are positively skewed, *geometric means* are typically used. The *median* of a variable is the middle value of its distribution; that is, half the distribution is below, and half is above, the median. The mean for the distribution of 500 birthweights given in Fig. 5.16.2A is 3.49 kg, and the median is 3.47 kg; these are very similar because of the symmetry of the distribution.

When data are ‘skewed’, as shown in Fig. 5.16.2B,C, the median is usually considered preferable to the mean (i.e. a better representative of the data), because the ‘extreme’ values may unduly influence the mean, whereas the median is little affected. In positively skewed data, the mean is greater than the median; in negatively skewed data, the reverse is true. The *mode* is the most frequently occurring value; a variable will have two modes if the distribution has two peaks (this can be checked using histogram plots as in Fig. 5.16.2). The mode has few useful applications in health statistics, as well as being difficult to handle mathematically. A *quantile* is a value cutting off a specified proportion of values of a random variable. Common particular cases are tertiles (two cut-off points, dividing the distribution into three equal areas of 33.3 per cent each), quartiles (25 per cent), quintiles (20 per cent), deciles (10 per cent), and percentiles (1 per cent). Note that the median is also the 2nd quartile, the 5th decile, and the 50th percentile. An extremely useful method of graphical display of a continuous variable is the *box plot*. These compactly incorporate information about location, variability, and shape of a distribution, as well as about outliers.

Measures of variability

From a statistical viewpoint, describing the variability of a quantity is just as important as describing its average value. The most useful measures of variability depend on the difference between individual values and the mean value (deviations). If all values equal the mean (no variability at all), all deviations are zero; large deviations indicate greater variability.

One way of combining deviations in a single measure is to first square the deviations and then average the squares. Squaring is done because we are equally interested in negative deviations and positive deviations; if we averaged without squaring, negative and positive deviations would ‘cancel out’. This measure is called the *variance* of the set of observations. It is ‘the average squared deviation from the mean’. Because the variance is in ‘square’ units, a second measure is derived by taking the square root of the variance. This is the *standard deviation* (SD), and is the most commonly used measure of variability in practice. The SD for the distribution of 500 birthweights given in Fig. 5.16.2A is 0.45 kg. The *range* of a variable is defined as the difference between the largest and the smallest values. For the birthweight data in Fig. 5.16.2A, the range is (from the raw data) $4.71 - 2.34 = 2.37$ kg. The range is susceptible to extreme values and depends on the number of observations; in general, the

Table 5.16.2 Sample of births in Brisbane, Australia, 1981, by birthweight

Birthweight (kg)	Number of babies (n = 500)	Percentage of babies (%)
2.3–2.49	6	1.2
2.5–2.69	10	2.0
2.7–2.89	19	3.8
2.9–3.09	63	12.6
3.1–3.29	71	14.2
3.3–3.49	94	18.8
3.5–3.69	78	15.6
3.7–3.89	65	13.0
3.9–4.09	41	8.2
4.1–4.29	26	5.2
4.3–4.49	20	4.0
4.5–4.69	6	1.2
4.7–4.89	1	0.2
Total	500	100.0

Fig. 5.16.2 Frequency distributions of characteristics of 500 babies born in Brisbane, Australia, 1981. (A) birthweight (kg), (B) gestation at delivery (weeks) for 500 babies, and (C) triceps skinfold thickness for 500 5-year-olds.

more observations, the greater the range. In practice, reporting the smallest to the largest values (2.34 to 4.71 kg) is more useful than the range itself.

The *coefficient of variation* is the ratio of the SD to the mean, usually written as a percentage. It thus expresses variation in relation to location or size. For the birthweight data, the coefficient of variation is $0.45 \text{ kg}/3.49 \text{ kg} = 0.129$ or 12.9 per cent: the SD is 12.9 per cent of the mean birthweight.

Probability distributions

Just as a sample mean or SD (if the sample is randomly drawn) reflect the population mean or SD, so the observed distribution in the sample reflects the distribution of values in the population. In practice, it is found that certain distribution shapes re-occur. It turns out to be extremely useful to give a particular mathematical form to these characteristic shapes, which can then serve as 'models' to enable further conclusions from samples.

The normal distribution

The distribution of birthweight for a sample of 500 full-term babies born in Brisbane, Australia, followed a roughly symmetric and bell-shaped curve. The empirical observation that distributions of continuous variables often follow this shape prompted

mathematicians to work on finding a mathematical or idealized representation to describe this.

The smooth curve so discovered has the mathematical formula:

$$f(X) = \frac{1}{\sqrt{2\pi} \times (\text{SD})} \exp\left(-\frac{1}{2 \times (\text{SD})^2} (X - \text{Mean})^2\right)$$

where 'exp' is the exponential (or antilog) function, and π ('pi') = 3.14159. X is the symbol given to the value of the variable in question (e.g. birthweight). Note the dependence on the mean of the population and its SD. This formula is known as the normal distribution and is a specific instance of a probability distribution; a mathematical description of the behaviour of a random variable (a variable whose values cannot be predicted with certainty). It can be thought of as an 'idealized' description of data, and can serve as a model upon which we base an analytical approach. The purpose of having an idealized model may be to 'smooth' the data or acquire some insight into the processes that underlie the generation of observations, by allowing us to test data against a given model. Once we have sample estimates for the mean and SD, we can fit this distribution to the sample. The mean controls the location of the central peak and the SD controls the extent of variability.

Many statistical procedures depend upon assuming an underlying probability model. Checking actual observations against these predictions can provide us with insight: if the probability model ‘fits’, then we can use features of the model to make further inferences or predictions about the population. If the model does not ‘fit’, then we need to find a more appropriate one. We would not regard the normal distribution a ‘good’ model for all distributions, such as those shown in Fig. 5.16.2B,C. Other probability distributions may be used in such instances; they may be more complex, because they incorporate additional information about the extent and type of skewness.

The usefulness of the normal model lies in the fact that its properties have been well studied. Specifically, for example, we know that approximately two-thirds of the distribution is enclosed by 1 SD either side of the mean, and approximately 95 per cent of the distribution is enclosed by 2 SDs either side of the mean. Fig. 5.16.3 shows the normal model fitted to the mean and SD of the sample of birthweight.

Within this normal model, 2 SDs either side of the mean takes us from $3.49 - (2 \times 0.45) \text{ kg} = 2.59 \text{ kg}$ to $3.49 + (2 \times 0.45) \text{ kg} = 4.39 \text{ kg}$. The area (or the area under the curve) between 2.59 and 4.39 kg in Fig. 5.16.3 (the outer set of vertical lines) is approximately 95 per cent of the total area.

In summary, the descriptive properties of the normal distribution are as follows:

- ◆ It describes a continuous variable across the entire numerical scale, although in practice values from an assumed normal distribution will be confined to a particular range.
- ◆ It is bell-shaped, and symmetrical about its mean value; that is, half of the distribution lies on either side of the mean.
- ◆ It is determined completely by its mean and SD.
- ◆ Limits set by the number of SDs either side of the mean predict the proportion of the distribution enclosed by these limits—for 1 SD, the area is 68 per cent of the distribution; for 1.96 SDs (≈ 2 SDs), it is 95 per cent; and for 2.56 SDs, it is 99 per cent. The number of SDs corresponding to different proportions is

Fig. 5.16.3 A normal distribution fitted using the sample of 500 birthweights (mean = 3.49 kg, SD = 0.448 kg) showing areas enclosed by 0.67, 1, and 2 standard deviations (SDs) either side of the mean.

calculated from the standard normal distribution, which has zero mean and a SD of 1.

The purpose of fitting a distribution in this way may simply be to obtain a ‘smoothed’ picture of a distribution. But we can use this ‘smoothed’ representation as a model for further calculations, such as estimating: (1) the proportion of babies whose birthweights are within a particular range or (2) the value of birthweight that cuts off a certain proportion of birthweights.

Sampling variability

The concept of sampling variability lies at the heart of what is known as *statistical inference*. Using a sample to estimate a mean or a proportion relating to a population, as opposed to examining the entire population, results in a considerable reduction in cost. This, however, results in some uncertainty about our estimate. Mathematical rules have been established which enable us to predict, within limits of probability, the sampling variability inherent in an estimation process based on random sampling. These rules contribute to the well-known practice of estimating confidence intervals (CIs), testing hypotheses, and fitting statistical models.

Sampling distributions

The *sampling distribution* of an estimate describes the chance variability we would expect to see in the distribution of sample estimates if we were to repeat our sampling process a large number of times. In practice we only have one sample and one estimate (of the mean, for example) and so must rely on mathematical theory to tell us the properties of the sampling distribution of the mean and therefore its precision.

Consider the example of taking a random sample of births, in order to estimate mean birthweight. As random sampling favours neither high nor low birthweights (i.e. it is unbiased), we expect that any particular sample mean will be as likely to be above the mean as below it. So, the first property governing the behaviour of random sampling is:

1. Irrespective of sample size, the sampling distribution of a mean has the same mean as the population mean.

Next, consider the size of the sample. Given an estimate is unbiased, how close is it likely to be to the true population value (i.e. the value we would obtain if we measured everyone in the population)? Intuitively, we would expect a random sample of 1000 members of a population to provide a ‘better’ or more precise estimate than a sample of 100. This results in the second property governing the behaviour of random sampling: governing the behaviour of random sampling:

2. The sampling distribution of a mean has variability (i.e. standard deviation) which decreases with the size of the sample.

The practical implication of (1) and (2) is that as the sample size N becomes larger, our sample estimate is more likely to be closer to the population mean.

Both properties of the sampling distribution of the mean have been mathematically demonstrated and further quantified. An important mathematical discovery related the expected SD of a sample mean to the sample size and the SD of the variable within

the population. The SD of a mean is more usually referred to as the *standard error of the mean* (SE).

The variability in the sample mean is defined by

$$\text{SD of the means} = \text{Standard error of the mean} = \frac{\text{SD of the population}}{\sqrt{N}}$$

where N is the size of the sample.

This shows that the larger the sample size, the less variable are the means, and that the greater the variability in the original measurements in the population, the more variable are the means.

In a remarkable mathematical result (the Central Limit Theorem), Pierre-Simon Laplace showed, in 1810, that the sampling distribution of the mean follows a normal distribution, once N becomes large enough, even when the original distribution itself does not follow a normal distribution! This puts us in a powerful position to predict the behaviour of sampling variability.

Confidence intervals

Confidence interval for a mean

The sample mean provides us with an estimate of the unknown population mean. Using the previous theory, we now know what to expect of its sampling variability.

Using our example of birthweights, and $N = 64$, we have an expected SE of 0.07 kg. Using the assumption of a normal distribution for sample means (the Central Limit Theorem), there is a 95 per cent chance that the error of our estimate is less than 0.14 kg (1.96×0.07). Another way of putting this is to say that there is a 95 per cent chance that:

- ◆ Sample mean – population mean < 0.14 kg, if the sample mean is greater than the population mean; and
- ◆ Population mean – sample mean < 0.14 kg, if the population mean is greater than the sample mean.

Reorganizing these, with 95 per cent probability, equivalent statements are:

1. Sample mean – 0.14 kg < population mean, if the sample mean is greater than population mean; and
2. Sample mean + 0.14 kg > population mean, if the population mean is greater than the sample mean.

Combining (1) and (2), we can say, with 95 per cent probability, that the limits (sample mean – 0.14 kg, sample mean + 0.14 kg) enclose the true (unknown) population mean. This is known as the *95 per cent CI for the mean*. We use other values (from the standard normal distribution) to obtain the CIs corresponding to different percentages. Generally:

$$\begin{aligned} \text{CI for a mean} &= (\text{sample mean} - k \times \text{SE}, \text{sample mean} + k \times \text{SE}) \\ &\quad \text{where SE} = \text{standard error of mean} \\ &= \frac{\text{SD}}{\sqrt{N}} \end{aligned}$$

where $k = 1.28, 1.645, 1.96$, and 2.56 for a 80 per cent, 90 per cent, 95 per cent, and 99 per cent CI, respectively.

In expressing this results we say ‘there is a 95 per cent probability that the interval (3284 g, 3516 g) contains the true mean birthweight’, *not* that ‘there is a 95 per cent probability that the population mean lies within (3284 g, 3516 g)’.

In practice, we do not know the SD of the population and usually replace it with the sample SD. This introduces very little error if the sample size is 50 or more. If the sample is small, we use a different multiplier for the standard error (i.e. a different k); this multiplier is obtained from the t -distribution (i.e. not the standard normal distribution), available in statistical software. We need to specify another parameter called *degrees of freedom* (df), which depends on the sample size: for sample size N , $\text{df} = N - 1$. Therefore, for $N = 30$, $\text{df} = 29$; for a 95 per cent CI, we use $k = 2.045$, instead of $k = 1.96$.

Note that a CI combines information regarding the size (location) of the parameter, the variability of values within a population, and the sample size used to estimate the parameter. It is thus a very useful quantity to summarize sample results.

Confidence interval for a proportion

We can also obtain a CI for proportions. The concept of a CI for a mean extends to a proportion, or indeed other epidemiological measures. Let us return to the birth attendant data from the Philippines (Table 5.16.1). We estimate that 224 of the 511 babies (43.8 per cent) were delivered by trained traditional birth attendants (TBAs). The principles underlying consideration of sampling errors for proportions are the same as for the mean. The Central Limit Theorem again assures us that, provided samples are large enough, sample proportions will have, approximately, a normal distribution.

The only different feature of the process of obtaining a CI for a proportion is the formula for the standard error of the estimate. The standard error of a proportion is

$$\text{Standard error of a proportion (SEP)} = \sqrt{\frac{p \times (1 - p)}{N}}$$

where p is the sample proportion, and N is the sample size.

In our example, we have $N = 511$, $p = 0.438$:

$$\text{Standard error of a proportion (SEP)} = \sqrt{\frac{0.438 \times (1 - 0.438)}{511}} = 0.022.$$

The formula for a CI for a proportion is then completely analogous to that for a mean. The 95 per cent CI for the proportion of babies delivered by TBAs is then $0.438 - (1.96 \times 0.022)$, $0.438 + (1.96 \times 0.022)$, or (0.395, 0.481). Expressing the result in percentages, an estimated 43.8 per cent of babies are delivered by TBAs, with a 95 per cent CI of (39.5 per cent, 48.1 per cent).

Basic principles and methods of comparative analysis

This section deals with some of the basic methods of analysis. Firstly, we consider situations in which we want to compare a set of mutually exclusive groups. This comparison may be on a number of different variable types, such as categorical or continuous health

outcome, or the prevalence or mean of a risk factor. Secondly, we introduce models, aimed at examining associations of variables, or patterns of risk factors.

Group comparisons

Many research questions in public health involve comparing groups. This may be in the context of an experimental or intervention study, a designed analytical study such as a cohort, case-control, or cross-sectional studies. Such analyses proceed in two phases: first we describe the pattern of the data *within* each group, using methods such as those described above, and then we evaluate the comparisons *between* groups.

The comparison between groups may initially be descriptive, but then we usually want an evaluation of the ‘significance’ of the differences we see; that is, are the differences compatible with sampling variability alone, or are there ‘real’ differences between the groups, which might be due to biological or other effects? If the differences are not attributed to chance, are they important from a clinical or public health perspective? We also often want to determine whether differences are due to ‘causal’ factors, and whether these causal factors are modifiable and so provide a basis for prevention or management. The judgement of causality involves additional evidence other than statistical analysis, such as biological plausibility, magnitudes of effects, and considerations of confounding. Although statistical analysis, particularly multivariable analysis (see later), can help provide some information, the final judgement of causality is a complex one.

Some examples of research questions, how they might be framed, and the nature of the variables involved are shown in Table 5.16.3.

If a relationship is being examined, it is usually important to consider whether variables have a role (or potential role) as ‘outcome’, ‘explanatory’, or ‘predictor’ variables. In Table 5.16.3, birthweight, length of labour, and stage of disease are outcome variables; mother’s height, number of previous births, and distance from the health centre are potentially explanatory variables (‘potentially’ because if it turns out there is no relationship, then one variable can hardly ‘explain’ the other). A variable may take on different roles in different questions; for example, number of years of schooling is an outcome variable in question 6 and an explanatory variable in question 7. So, for the purpose of classifying variables as outcome or explanatory, what matters is the orientation of the question (which event comes first?).

Analyses of relationships depend on the types of variables involved, and there may be several valid methods from which to choose.

Comparing proportions or percentages

The first step in examining the relationship between two categorical variables is usually to cross-classify them; that is, break down one variable by the values of another. This is usually displayed in a contingency table, which shows all combinations of values. Consider an example (Table 5.16.4) taken from a study of skin cancer in Queensland, Australia (Green et al. 1999).

Table 5.16.3 Some research questions that involve relationships between two variables

Question	Variable combination
1. Does height influence the birthweight of her child?	Continuous–Continuous
2. Is there an association between length of labour and the number of previous births a woman has had?	Continuous–Discrete
3. Do people present at a later stage of disease if they live a greater distance from the health centre ?	Ordinal–Continuous
4. Do different ethnic groups have different calcium intake ?	Nominal–Continuous
5. Does the number of sunburns a person has experienced predict the number of skin cancers they have?	Discrete–Discrete
6. Does the number of years of schooling a child acquires depend on his or her birth order in the family?	Discrete–Ordinal
7. Does the number of years of schooling a girl acquires influence her paid employment status in later life?	Discrete–Nominal
8. Do different socioeconomic groups present with different degrees of disease severity ?	Ordinal–Ordinal
9. Does diagnosis at presentation depend on socioeconomic group ?	Nominal–Ordinal
10. Does susceptibility to skin cancer depend on skin colour ?	Nominal–Nominal

Table 5.16.4 Numbers of people with a non-melanoma skin cancer (NMSC) diagnosed on a sun-exposed site in the period 1993–2006, by skin type, as reported in 1992

	No NMSC	One NMSC lesion only	Multiple NMSC lesions	Total
Always burn	236 (69.4)	50 (14.7)	54 (15.9)	340
Burn, then tan	866 (78.8)	112 (10.2)	121 (11.1)	1099
Tan only	148 (82.7)	16 (8.9)	15 (8.4)	179
Total	1250 (77.3)	178 (11.0)	190 (11.7)	1618

Figures in parentheses are percentages within each skin type.

Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al., Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

A contingency table should include *all* combinations of *all* categories of each variable. The overall incidence of skin cancer in the follow-up period is 22.7 per cent (combining single and multiple lesions), but incidence is higher in those reporting a skin type that sunburns, with or without tanning (21.2 per cent and 30.6 per cent, respectively), than in those whose skin tans without burning (17.3 per cent).

If we repeat the skin cancer study with another sample of 1600 or so participants, we will obtain slightly different results, even if we follow exactly the same procedures. This is due to sampling variability: within our study population, individual people with the same characteristics will have different skin cancer outcomes. How do we take this into account in our interpretation of findings? To simplify the example, consider the comparison of the three skin types, combining single and multiple lesions. The first step is to calculate what we would expect to see if people with different skin types produced on average, the *same distribution of responses*. In other words, what would we expect to see if sampling variability was the *only* factor operating to produce variability in responses? The answer is: the same distribution of skin cancer within each skin type. The results of calculating these ‘expected’ results are shown in Table 5.16.5.

The figures in parentheses in the table are called *expected frequencies*; that is, the numbers expected if skin type is unrelated to skin cancer. Note that the marginal totals of observed and expected frequencies are the same. We have observed more skin cancer in the ‘Always burn’ group (about 27 more cases) than expected on the basis of no difference between skin types and less in the ‘Tan only’ group (10 fewer cases). These differences relate either to:

1. Sampling variability alone (i.e. no additional risk of skin cancer associated with skin type).
2. Sampling variability *plus* an additional risk of skin cancer associated with skin type.

The statement that, in the study population, skin type is unrelated to skin cancer is called the *null hypothesis*, and is the first step in any formal evaluation of the role of chance.

The Pearson chi-squared test

The statistic called the *chi-squared test statistic*, developed by Karl Pearson, enables us to summarize the differences between observed and expected frequencies, so we can make a decision as to the significance of these. Calculations are shown in Table 5.16.6.

Table 5.16.5 Numbers of people with a non-melanoma skin cancer (NMSC) diagnosed on a sun-exposed site in the period 1993–2004, by skin type, as reported in 1992, and numbers expected (in parentheses) if the distributions of skin types are the same in each group

	No NMSC lesions	One or more NMSC lesions	Total
Always burn	236 (262.7)	104 (77.3)	340
Burn, then tan	866 (849.0)	233 (250.0)	1099
Tan only	148 (138.3)	31 (40.7)	179
Total	1250	368	1618

Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al., Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

Table 5.16.6 Calculation of the chi-square statistic for data in Table 5.16.5

	No lesions	One or more lesions
Always burn	$\frac{(236 - 262.7)^2}{262.7} = 2.71$	$\frac{(104 - 77.3)^2}{77.3} = 9.22$
Burn, then tan	$\frac{(866 - 849.0)^2}{849.0} = 0.34$	$\frac{(233 - 250.0)^2}{250.0} = 1.16$
Tan only	$\frac{(148 - 138.3)^2}{138.3} = 0.68$	$\frac{(31 - 40.7)^2}{40.7} = 2.31$
Sum of all	$\frac{(\text{Observed Frequency} - \text{Expected Frequency})^2}{\text{Expected Frequency}}$ $= 2.71 + 9.22 + 0.34 + 1.16 + 0.68 + 2.31$ $= 16.42$	

Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al., Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

The formula for the chi-squared statistic is:

$$X^2 = \sum_{i=1}^{i=k} \frac{(O_i - E_i)^2}{E_i}$$

where k is the number of cells in the table.

The following is observed:

- ♦ The smallest value of X^2 that can occur is 0, when all individual terms have their smallest value as 0 and corresponding expected and observed frequencies are exactly equal.
- ♦ The value of X^2 increases as differences between observed and expected frequencies increase.
- ♦ The larger the sample, the larger the value of X^2 , for a given strength of association: if we double the sample size, for example, we double the calculated value of X^2 .

So, the measure (X^2) increases as the observed frequencies increasingly depart from the expected frequencies. Thus small values of X^2 are consistent with (1) above, but increases in X^2 suggest that (2) is the underlying explanation.

The calculated value of X^2 is 16.42 (Table 5.16.6). But how large does X^2 need to be before we can decide in favour of (2) over (1)? Is there a cut-off point? The mathematics of this question have been solved: for any given value of X^2 we can find the probability that this value, or one larger than it, will occur if the observed differences are due to chance alone; that is, if (1) is true. The relationship between values of X^2 and the probability of such values occurring is expressed in the *chi-squared distribution*. Tables for the chi-squared distribution are available in standard textbooks, or values can be obtained from statistical software. The probabilities depend on another parameter, the *df*, which depends on the number of row and column categories in the contingency table. If the table has r rows and c columns, $df = (r - 1) \times (c - 1)$. For Table 5.16.6, there are three rows and two columns: $df = (3 - 1) \times (2 - 1) = 2$.

The probability, referred to as the *p*-value, of getting $X^2 = 16.42$, or larger, is 0.0003. So if (1)—sampling variability—is the sole explanation for the observed treatment difference, the probability of seeing such a large value of X^2 is 0.0003, or 0.03 per cent or 1 chance in 3333. Because this is very small, we would feel inclined to reject (1) in favour of (2). In practice, the most common cut-off point to use in order to make this decision is $p = 0.05$ or 5 per cent.

We then say that there is a *statistically significant difference* between skin types in risk of skin cancer ($p = 0.0003$). From Table 5.16.6, we see that the ‘Always burn’ skin type contributes by far the most to the value of X^2 , so we could conclude that this category is responsible for most of the statistically significant finding.

Limitations of the Pearson chi-squared test

The use of the *Pearson chi-squared test* involves an important underlying assumption—that the observed frequencies are independent. If, for example, instead of skin type we were comparing pre- and post-intervention incidence of skin cancer within the same sample of people, the observations would not be independent, because outcomes for the same person would be expected to be related and the Pearson chi-squared test should not be used.

The chi-squared test also depends on samples being ‘large enough’ to be valid. For contingency tables, ‘large enough’ has been found to depend on the size of the expected frequencies. The rule of thumb has emerged that if around 1 in 5 (or 20 per cent), or more, of expected frequencies are less than 5, then the test is not valid. Statistical software provides simulation or permutation tests which give an estimated *p*-value directly, which is then interpreted in the usual way.

We had decided to reject the null hypothesis based on a probability cut-off point in order to distinguish between (1) and (2). This decision might have been incorrect. It is unlikely (about 1 chance in 3333), not impossible, that a value of $X^2 = 16.42$, or larger, could occur if (1) were true. Rejecting the null hypothesis, concluding there is a significant difference when there is not, is a *type 1 error*. The reverse error, failing to reject the null hypothesis when it is false or concluding there is no difference when there really is, is called a *type 2 error*. This error typically arises when we have a small sample size, and our data are insufficient to detect a difference.

Table 5.16.7 summarizes the four possible outcomes from a statistical test of a hypothesis, according to whether there is a real effect (e.g. a real difference) and whether the test statistic is significant (i.e. the *p*-value is small). A type 1 error is a false-positive finding and a type 2 error is a false-negative finding.

Asserting that a difference, or an association, is ‘significant’ does not mean that the association is ‘strong’ or that it is causal.

Table 5.16.7 Type 1 and type 2 errors

		True effect	
		Null hypothesis true	Null hypothesis not true
Statistically significant effect (reject null hypothesis)	No	✓	Type 1 error (false-positive)
	Yes	Type 2 error (false-negative)	✓

A statistically significant finding means that the size of the difference or association is larger than would be likely to occur by chance alone (i.e. sampling variability alone) in the absence of any real association. These techniques can be applied to larger contingency tables, although sometimes further examination of the data may be needed to identify the nature of the differences.

The chi-squared test explores all variability in proportions in a contingency table. However, sometimes we want to examine a more specific type of association, and the chi-squared test may not be the best one to use. An example of such a situation occurs when we want to examine trends in proportions.

Suppose we regarded the skin type groups (in order) in Table 5.16.5 as indicative of an increasing inflammatory reaction to sun exposure and wanted to test a hypothesis about increasing risk of skin cancer with increasing inflammatory response (rather than just variability in risk with skin type, whatever the pattern). That is, we want to treat the variable as ordinal rather than nominal—we need a statistical test that specifically looks for a trend pattern. Various options are available, which usually involve assigning an increasing score to the categories of the ordinal variable. Tests for these will be discussed in the subsection for regression modelling of binary variables.

Comparing means

Suppose we want to examine whether a child’s birthweight depends upon his or her mother’s marital status. We know that the distribution of birthweight, a continuous variable, can be summarized by its mean and standard deviation. So we examine these summary measures within values of the categorical variable (marital status, a nominal variable) to see how the continuous variable varies with the categorical variable. Table 5.16.8 shows the results.

If the frequency distribution of a continuous variable is approximately normal (as it is for birthweight), then it is described fully by its mean and SD, which is why we use these measures in the example. In other cases, such as skewed distributions, we might use the median or the geometric mean as a measure of location and the interquartile range as a measure of variability, and present these instead of, or along with, the mean and standard deviation.

These results show that, compared to ‘Married’ women, women who have ‘Never married’ have slightly heavier babies (by 0.07 kg), whereas women ‘Living together’ and ‘Other’ have slightly lighter babies (by 0.19 kg and 0.17 kg, respectively). These differences seem comparatively small, but would be regarded as important differences (by comparison with other risk factors that decrease birthweight, e.g. smoking). The mean for married women is very close to the overall mean, because they make up most ($363/500 = 72.6$ per cent) of the sample. We now need to make an assessment of the role of chance in producing the observed differences. We know that some variability in observed means is due to sampling error, but could sampling error be the complete explanation? The crucial question is whether the means differ more than would be expected by chance alone.

The sampling variability of a mean is assessed by its standard error of the mean (SE) which has earlier been used to derive a CI for the true mean. We can apply these techniques to the data in Table 5.16.8, examining mothers’ marital status and birthweight (Table 5.16.9).

Table 5.16.8 Mean, standard deviation (SD), and range of birthweight, by marital status of mother, for a group of Brisbane babies born in 1984–1988

Marital status	N	Mean (kg)	SD (kg)	Minimum (kg)	Maximum (kg)
Married	363	3.57	0.42	2.33	4.85
Never married	70	3.64	0.44	2.34	5.06
Living together	53	3.38	0.42	2.27	4.18
Other	14	3.40	0.40	2.86	4.28
Total	500	3.56	0.43	2.27	5.06

Table 5.16.9 Mean birthweight (kg), standard errors (SE), and 95 per cent confidence intervals (CI), by marital status of mother, for a sample of Brisbane babies born in 1984–1988

Marital status	N	Mean (kg)	SE (kg)	95% CI
Married	363	3.57	0.022	(3.53, 3.62)
Never married	70	3.64	0.052	(3.53, 3.74)
Living together	53	3.38	0.058	(3.27, 3.50)
Other	14	3.40	0.108	(3.16, 3.63)
Total	500	3.56	0.019	(3.52, 3.59)

Source: data from Najman, J.M. et al, Cohort profile: the Mater-University of Queensland Study of Pregnancy (MUSP), *International Journal of Epidemiology*, Volume 34, Issue 5, pp. 992–7, Copyright © 2005.

Note the variability in the standard errors due to the variability in the sample size: the largest group ('Married' women) has the smallest standard error and the smallest group ('Other') has the largest standard error. Correspondingly, the CIs vary greatly in their widths. For 'Married' and 'Never married' mothers the CIs overlap considerably, but the 'Married' group has a very narrow CI, which does not overlap the 'Living together' category. We might feel that the difference among 'Married' and the 'Never married' could be explained by sampling variability, but that the difference between 'Married' and 'Living together' categories could not. Sometimes overlap or non-overlap of CIs is used in this way, but if we wish to make a formal statement about the difference between means then we must make a formal statistical test.

The two-sample *t*-test

The first step of a formal statistical test is to formulate a null hypothesis. In this case, the null hypothesis is that (true) mean birthweights do not vary among marital status groups. First consider the difference between birthweights of children of 'Married' (3.57 kg) and 'Never married' (3.64 kg) mothers—a difference of 0.07 kg. The next step involves assessing the role of chance in producing this observed difference if there is no difference in the population means. As before, we need to obtain the probability of getting a difference of 0.07 kg, by chance, if the null hypothesis is true. We evaluate this by first calculating a *t*-statistic. Perhaps not surprisingly, the test statistic depends on:

- ◆ The size of the difference between the means.
- ◆ The standard errors of the means.

Therefore:

$$t = \frac{\text{Difference between the means}}{\sqrt{\text{Sum of (SE)}^2}}$$

with degrees of freedom (df) = sum of sample sizes – 2.

This is called the *two-sample t-test*. The larger the difference between the two sample means, and the smaller the standard errors (or the larger the samples), the larger the value of *t*. As for the chi-squared test, once we have a calculated value and a value for the degrees of freedom, we obtain a *p*-value using statistical software.

For the comparison of birthweights of children whose mothers are 'Married' or 'Never married', we have:

$$t = \frac{3.57 - 3.64}{\sqrt{0.002^2 + 0.052^2}} = -1.24$$

with degrees of freedom (df) = 363 + 70 – 2 = 431.

From statistical tables, we see that the *p*-value is > 0.10 (using df = infinity (∞)). The probability that such a difference could occur by chance is quite high. We then attribute the observed difference to sampling variability and conclude the difference is not significant.

Analysis of variance

For the example of mothers' marital status and birthweight, we could carry out more *t*-tests, looking at the difference between other pairs of groups. However, it is considered bad practice to 'search' for significance in this way. A more acceptable practice is to carry out a 'global' test on the set of four means, to see if there is any significant variability among the means as a set, without specifying any particular pair of means. Pairwise differences may then be examined post hoc, once overall variability has been established. The technique used for this global test on a set of means is called *analysis of variance* (ANOVA). The null hypothesis is that there is no variation in the population means for all groups. Effectively, we assume all mothers, irrespective of marital status, belong to the same population, as far as their babies' birthweights are concerned. No new conceptual issues arise in this analysis.

Again we work out a test statistic, now called an *F*-statistic. This test statistic depends on:

- ◆ The variability among the means.
- ◆ The standard errors of the means.

Now we have 2 df to work out: the so-called ‘numerator’ df is the number of groups minus 1 and the ‘denominator’ df is the total sample size minus the number of groups being compared.

We would usually use statistical software for ANOVA, which will also give us a p -value. In this case, the F -statistic is 14.01, with $df = (3, 497)$, and $p = 0.0029$. This is smaller than our usual cut-off point of 0.05, and we conclude that there are significant differences in birthweight among the marital status groups. These differences obviously arise from the ‘Living together’ and ‘Other’ groups.

If we had decided not to reject the null hypothesis, the matter would have ended there. When we do reject the null hypothesis, we might want to examine the pairwise differences using t -tests. Although opinions vary, sometimes modified versions of the t -test are used to take into account the multiple comparisons that might be involved in such examination. Multiple comparisons increase the overall risk of a type 1 error (i.e. finding at least statistically significant result just by chance).

Assumptions of the two-sample t -test and ANOVA

The two-sample t -test and ANOVA have important underlying assumptions. These are as follows:

- ◆ If the sample is small, the mean is based on a variable with a normal distribution; if the variable does not have a normal distribution, the sample is large enough for the Central Limit Theorem to apply to the distribution of the mean.
- ◆ The SDs within each group are approximately equal.
- ◆ The samples are independent observations; that is, separate groups of individuals.

We have already established that the distribution of birthweight is quite close to a normal distribution, so the first assumption has been met. What about the second? Inspection of the ‘SD’ column in Table 5.16.8 confirms this—the SDs vary only slightly.

A statistical test, called Bartlett’s test, can be used to determine whether SDs are significantly different. Some statistical software automatically carries out this test when an ANOVA is requested. Alternative tests are available in such a situation.

There are two main options for dealing with non-normal distributions: transformations and non-parametric tests.

Transformations: it is sometimes possible to transform the variable to make a normal distribution, and then carry out the t -test or ANOVA on the transformed variable. If a variable has a positively skewed distribution, the log transformation is sometimes used to give a more symmetric distribution, closer to the normal distribution. Many transformations are available, but there is no guarantee that any will work in any particular case. The distribution of the transformed variable needs to be examined to confirm this.

Non-parametric tests: if a transformation cannot be found, it is possible to use a non-parametric test. These do not require the first two assumptions, but still require independence between observations (the third assumption). Instead of a t -test, we use the Wilcoxon–Mann–Whitney test to get a p -value for comparing two means; instead of ANOVA, we use the Kruskal–Wallis analysis of variance to obtain a p -value for comparing two means.

If the assumptions are met and non-parametric tests are used, these tests will have less ability to detect differences between means; that is, they will result in larger p -values than the t -test or ANOVA and be less likely to reject the null hypothesis. Usually researchers want to make the maximal use of their data, and carry

out the most sensitive tests possible, so they prefer to use tests based on the normal distribution if possible.

Repeated measurements of a quantitative variable

The questions in Table 5.16.3 are about relationships between two variables, each of which is essentially different from the other. Sometimes our question relates to whether a single variable changes over time. Suppose we are investigating the effectiveness of an intervention to improve the nutritional status of children. In this case, we might measure the nutritional status of each child within the sample of children before and after the intervention. At first sight, this looks similar to the previous case: there are two variables, nutritional status before intervention and nutritional status after intervention. But this is different because we are really observing one variable at two different times. We expect measurements taken on the same individual at two different times to be related. This relationship needs to be taken into account when the effect of a second variable (intervention) is being evaluated.

In a trial to examine the effectiveness of a dietary intervention, 17 participants had vitamin A intake (in micrograms) assessed at baseline and 6 months later, to see whether the dietary intervention helped increase vitamin A intake over the 6-month period (Table 5.16.10). At first sight, we might see this as a situation for a two-sample t -test, comparing mean vitamin A intake at baseline

Table 5.16.10 Vitamin A intake levels (micrograms) at baseline and 6 months post-intervention

Person	Baseline	6 months	Change (6 months – baseline)
1	120	124	4
2	122	135	13
3	126	140	14
4	131	130	–1
5	135	169	34
6	157	189	32
7	160	176	16
8	181	196	15
9	195	223	28
10	200	254	54
11	205	267	62
12	211	289	78
13	215	301	86
14	220	227	7
15	246	305	59
16	255	278	23
17	278	299	21
Mean (SD)	185.7 (49.6)	217.8 (65.4)	32.1 (26.3)

and at 6 months. This is not appropriate because the third assumption for the two-sample *t*-test—*independence of the groups being compared*—has not been met.

Almost all 6-month values are higher than baseline values, although some individual differences are quite small. The appropriate summary statistic to compare paired repeated measurements of a continuous variable is the *mean change* within individuals. For each participant, we subtract baseline vitamin A levels from 6-month values. The mean and SD of these individual changes are then calculated. Hence, for matched data, we finally deal with one variable (i.e. change after intervention) and not two variables. In this example, the mean change in vitamin A levels was 32.1 micrograms, with a range of changes from -1 to +86 micrograms and a SD of 26.3 micrograms. Where the distribution of the observed changes is not normal, a more valid summary would be the median.

To get a 95 per cent CI for the mean change, we first calculate the standard error of the mean change in vitamin A intake, which is

$$SE(\text{change}) = \frac{SD(\text{change})}{\sqrt{N}} = \frac{26.3}{\sqrt{17}} = 6.4 \text{ micrograms.}$$

The 95 per cent CI = (mean change - 1.96 × SE(mean change), mean change + 1.96 × SE(mean change)) = (19.5, 44.6).

Notice that the lower limit of this 95 per cent CI is well above zero, so we have considerable confidence that the change is positive, at least.

We can formally test the null hypothesis that the true increase is zero by calculating a *t*-statistic, as follows:

$$t = \frac{\text{mean change}}{SE(\text{change})}.$$

This is referred to as the *paired or one-sample t-test*, because it assumes paired measures, and we want to evaluate the significance of the change (or more generally, the difference) within the paired values. The larger the mean change, and the smaller the standard error (or the larger the sample), the larger the value of *t*.

Once *t* and its df are calculated, we obtain a *p*-value from *t*-tables or statistical software. For the paired *t*-statistic on *N* pairs, the df is *N* - 1. We calculate *t* = 5.02, with 16 df, for which *p* = 0.0001. It is extremely unlikely that such a difference could occur by chance, or sampling variability, alone, with no effect attributable to the intervention. So we reject the null hypothesis and conclude that the intervention has increased dietary intake by an estimated 32.1 micrograms per day, with a 95 per cent CI of (19.5 micrograms, 44.6 micrograms).

Again, this *t*-test is based on the assumption that the change in vitamin A level is normally distributed. If this assumption cannot be made, a non-parametric counterpart test can be used—the Wilcoxon signed-rank test.

Correlation and regression

We now examine similar questions, when both variables being considered are continuous. This leads to some different measures of data presentation, and different techniques for assessing the significance and size of associations.

Scatter plots

Suppose we are interested in the relationship between birthweight and maternal weight prior to pregnancy, both continuous variables. An efficient method of displaying such a relationship visually is to use a scatter plot in which each point represents a particular mother (weight)–child (birthweight) pair. Fig. 5.16.4 shows that heavier mothers tend to have heavier babies. Although such a pictorial representation of the relationship is useful, we usually summarize the relationship more concisely, with a ‘coefficient of association’.

Coefficients of association

Various coefficients of association have been developed for quantitative measures, with some common properties. These include the following:

- ◆ A value of zero for the coefficient means no association.
- ◆ A negative value for the coefficient means that one variable increases as the other decreases.
- ◆ A positive value for the coefficient means that the variables increase or decrease together.
- ◆ The range of the coefficient is from -1 to +1. Attainment of -1 or +1 is said to be ‘perfect association’.

For the relationship shown in Fig. 5.16.4, we would expect a measure of association to be a positive value, somewhat less than 1.

Pearson correlation coefficient

The most commonly used measure of association is the Pearson correlation coefficient (*r*), used to describe the linear relationship between two continuous variables. If values of both variables increase together, *r* will be positive. If values of one variable increase as those of the other decrease, *r* will be negative. In the earlier example, ‘*Y*’ is birthweight and ‘*X*’ is maternal weight, corresponding to our scatter plot in Fig. 5.16.4. The correlation coefficient is estimated as +0.50. Is this a ‘high’ or ‘strong’ correlation? As a rough guide, in biostatistics, 0–0.15 is usually regarded as

Fig. 5.16.4 Scatter plot and regression line of birthweight (g) and maternal pre-pregnancy weight (kg) fitted by least squares for a group of 16 term Brisbane babies, born in 1984–1988.

Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al, Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

a 'low' correlation, 0.16–0.4 as a 'modest' correlation, 0.41–0.7 a 'moderate' correlation, and above 0.7 a 'high' correlation, although context usually matters.

Significance of the correlation coefficient

The value of 0.5 obtained may be considered moderate in magnitude. A separate issue is that of significance. This examines the role of chance or sampling variability in observing a coefficient of this size. We need to obtain the probability that a coefficient as large as 0.5 would be observed by chance in a sample of this size if maternal weight and birthweight had no true relationship (a true correlation coefficient of 0).

In the case of the Pearson correlation coefficient, the p -value is obtained directly from tables or statistical software. As before, we need to calculate the df parameter which depends on the sample size N . In this case, $df = N - 2$, or $16 - 2 = 14$. This gives $p = 0.048$, just less than the conventional cut-off. So the correlation coefficient could be described as 'significant' or, more completely, as 'significantly different from zero'.

Types of association and correlation

Fig. 5.16.5 shows various types of association and how they would be described. It is important to note that the correlation coefficient measures only linear relationships; alternatively, we might say the correlation coefficient only measures that part of the relationship which is linear. A linear relationship is one in which a straight line approximates the relationship.

Note that the lower right graph in Fig. 5.16.5 would give a correlation close to zero correlation for the Pearson coefficient. The reason for this is that the data are non-linear, even though there

appears to be a relationship between the two variables. Thus, the Pearson coefficient only measures strength of a linear relationship. If we wanted to estimate strength of association for a non-linear relationship, we would have to specify a particular non-linear form.

Regression

To illustrate the regression approach to analysis, we use the data in Fig. 5.16.4. We wish to 'model' the association between the two variables by fitting a straight line to the data, as follows. A linear model involving one dependent and one independent variable is expressed as:

$$Y = \alpha + \beta X + e.$$

In setting up a regression model, one variable, usually denoted Y , called the *dependent variable* (or *outcome*), is the variable to be predicted or modelled. The other variable, usually denoted X , is sometimes called the *independent variable* (or better, the *predictor* or *explanatory variable*) and is the variable used to predict or explain Y . The formula of the model assumes Y has a straight-line relationship with X . The symbols α and β represent the intercept and the slope, respectively, of the line on a scatter plot of Y versus X . The parameter β is called the *regression coefficient*, and is a measure of how much Y changes for a unit (e.g. 1 kg of maternal weight) change in X ; α is usually not of interest. The quantity e measures the 'error'—given that it is very unlikely such a simple model will describe data such as that in Fig. 5.16.4, we allow for the 'error' to have a distribution. In this case, for each value of X , the errors are assumed to have a normal distribution about the predicted value $\alpha + \beta X$.

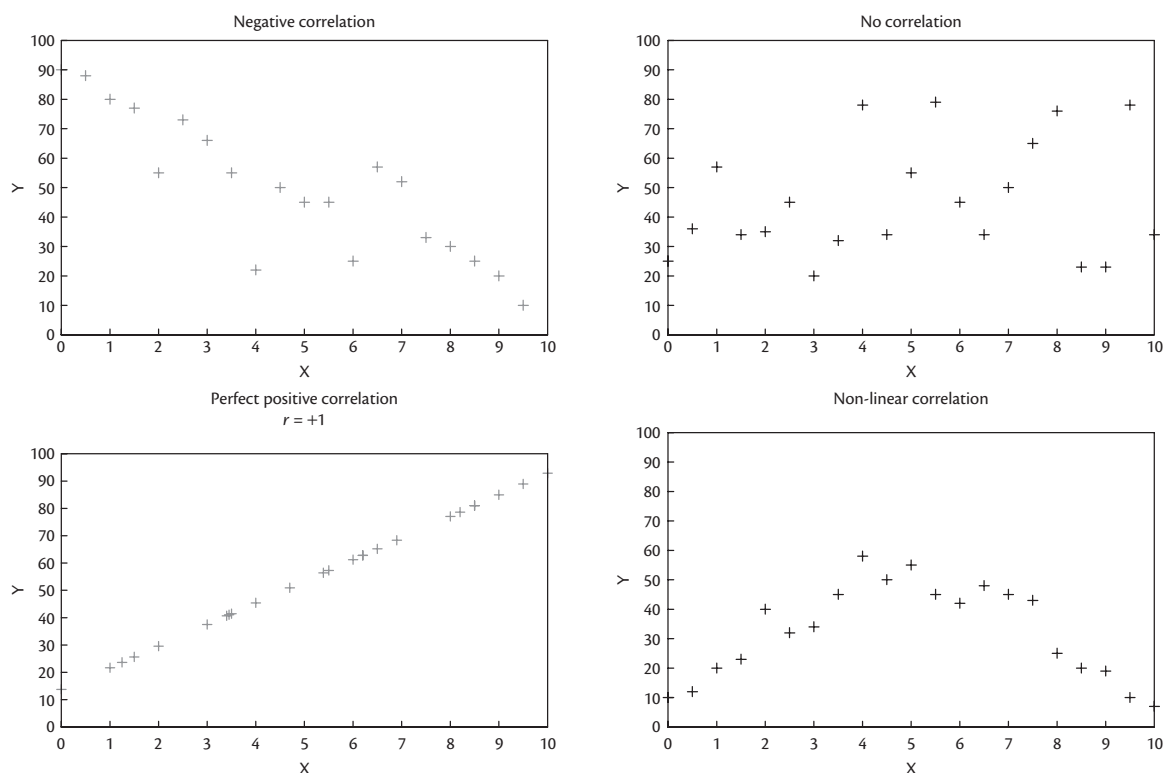

Fig. 5.16.5 Types of association.

A mathematical algorithm is needed to estimate α and β —the simplest of these is the *method of least squares* which minimizes the squared differences between observed values and those predicted by the model.

For the birthweight data in Fig. 5.16.4, we obtain the following model:

$$Y = 1,124 + 45.5X.$$

That is, birthweight increases by 45.5 g for every 1 kg of mother's weight. So mothers who differ by, say, 10 kg in their pre-pregnancy weight would expect to have babies, on average, who differ by 455 g in birthweight. Standard errors and CIs can be calculated for a regression coefficient. In this case, the 95 per cent CI for the regression coefficient is (4.5, 86.5). Although this CI is quite wide, it excludes the value 0, which would correspond to no relationship between mother's weight and child's birthweight (a horizontal line on Fig. 5.16.4).

We can also formally test for the statistical significance of the regression coefficient, using statistical software. For this example $p = 0.03$, which is small enough to conclude the relationship is significant.

The model can be used for prediction. If a pregnant woman has a pre-pregnancy weight of 50 kg, we can predict that her infant will have a birthweight of $Y = 1124 + (45.5 \times 50) = 3399$ g.

Assumptions of correlation and regression analyses

Correlation and regression coefficients are estimated on an assumption of a linear association. To make inferences (test hypotheses or calculate CIs), however, you need to make additional assumptions. These are as follows:

- ◆ For correlation analyses, the two variables involved have joint normal distributions.
- ◆ For regression analyses, the outcome (dependent variable) has a normal distribution.
- ◆ For correlation and regression analyses, the samples are independent observations; that is, all pairs of observations are independent.

We have already established that the distribution of birthweight is quite close to a normal distribution, so the second assumption needed for regression analysis is met. What about the others? What do we do if the assumptions are not met? Again there are two main options: transformations and non-parametric correlation coefficients.

- ◆ *Transformations*: transformations can be used, as described in the subsection on *t*-tests and ANOVA.
- ◆ *Non-parametric correlation coefficients*: if a transformation cannot be found, it is possible to use a non-parametric test instead. These do not require either of the two distribution assumptions mentioned here. Instead of a Pearson correlation, we use the Kendall (τ or τ) or Spearman correlation coefficient (r_s).

The successful fitting of a straight line to the data does not establish causality. Although we predict that babies whose mothers' weights differ by 1 kg will have birthweights differing on average by 45.5 g, we cannot predict that increasing a mother's weight by 1 kg will cause an increase of 45.5 g in her child's birthweight. Observing an association between an outcome and a potential risk

factor is, however, the first step in examining causality; we then have to consider possible explanations, which include chance, bias, and confounding. The results of a significance test enable us to assess the role of chance, but bias and confounding are crucial to consider. Multivariable statistical modelling is one approach to examining confounding; and is dealt with later in this chapter.

Survival data

In a cohort study, if an event or disease of interest is likely to occur in most participants, then interest centres on the actual time till the event, rather than the occurrence of the event itself. Examples include time to death following a diagnosis of breast cancer, time to remission of disease following treatment, or time to cessation of breastfeeding, in a cohort of infants. Such data are referred to as *survival data* or *failure time data*. A person's 'survival time' is his or her time from entry in the study until the occurrence of the event. The distribution of survival times is often very skewed and may be bimodal (e.g. if significant postoperative mortality is followed by increased then gradually decreasing prospects of survival).

Survival data may be *censored* if there are participants who do not experience an event because the study ends before this occurs, are 'lost to follow-up' (because of, e.g. migration or death), experience another type of event which precludes the event of interest (e.g. death from another cause), or cease to be eligible for the study (e.g. in a study of under-5s, children are ineligible after their fifth birthday). In such instances, the person's survival time cannot be known precisely, only that it is *at least* a certain amount. *Survival analysis* enables use of all of a person's 'at-risk' time, irrespective of whether an event is experienced. An additional feature is that it allows the incidence rate to vary for the entire period of observation.

The Worcester Heart Attack Study (WHAS) examined factors associated with survival rates following acute myocardial infarction (MI) (Tonne et al. 2005). Data were collected from 1975 to 2001, on 500 MI patients' hospital admissions in the Worcester, Massachusetts Standard Metropolitan Statistical Area. Data analysis focuses on time from admission to death, or time from admission to the last follow-up, if the patients were still alive. Of the 500 patients, 215 (43 per cent) died within their follow-up period.

The analytical approach is to divide the follow-up time into short periods, called *risk sets*, and count events that occur within each risk set, as a fraction of all people who were in the study for that period. The latter is particularly important: people will drop out of the analysis because they have experienced the event (died) or had finished their follow-up period. These fractions are then manipulated in a process attributed to Kaplan and Meier (1958) to form a curve that shows the estimated probability of survival to that time. Results for fitting this curve to the WHAS data overall and to two subgroups (with and without complications at admission) are shown in Fig. 5.16.6, with 95 per cent CIs.

'Notice that mortality is highest immediately after the initial MI, with only about 70 per cent surviving the first year, but flattens a little at about 2 years. This analysis yields more information than simply examining mortality rates. The survival curve can also be used to estimate the median survival, the length of time corresponding to 50 per cent survival: project from a horizontal line at survival = 0.5 to the horizontal axis to give an estimated 50 per cent of people survive to 5 years or more (i.e. the 5-year survival is 50 per cent).

Fig. 5.16.6 Survival curves for patients with MI, overall and according to presence or absence of complications at time of admission (Worcester Heart Attack Study). Those without complications is the upper graph on the right.

Source: data from Tonne C, et al., Long-term survival after acute myocardial infarction is lower in more deprived neighborhoods, *Circulation*, Volume 111, pp. 3063–70, Copyright © 2005 American Heart Association, Inc. All rights reserved.

Other quantiles can similarly be estimated. Kaplan–Meier survival curves can be formally compared using the Wilcoxon or logrank tests (Martinez et al. 2010) (Doi and Williams 2013).

Additional comments on censoring

'Whenever a participant experiences an event which precludes them from experiencing the event of interest, they are censored at that point. For example, if, in the WHAS, the event of interest is death from cardiovascular disease, then a patient who experiences death from cancer is considered censored at the time of death. We also assume that censoring is independent—that is, that people with censored observations have the same future risk as those that are not censored. This is quite a strong assumption. For example, suppose we are examining survival of patients admitted to an intensive care unit. If follow-up ceases at discharge then, given that those discharged are more likely to have a better prognosis than those not discharged, censored observations would be likely to have a lower risk. If drop-outs differ from non-drop-outs this is also likely to lead to dependent censoring.

A specific example of this occurs in 'competing risk' models. In the example given earlier for death from cardiovascular disease, and censoring by death from cancer, we need to consider whether a person who dies from cancer would have the same future risk (had she/he not died from cancer) of death from cardiovascular disease. This may seem plausible. However if, in a series of patients with obesity, the event of interest is death from cardiovascular disease, death from diabetes would be a competing event, since it is likely that risks of these outcomes would be associated. In such instances it is argued that the methods described earlier would result in biased estimates of survival. The appropriate analyses are complex, essentially involving the joint analysis of the cumulative incidence of both the event of interest and any competing event(s)' (Doi and Williams 2013).

Multivariable analysis

This section deals with the situation where we have more than one variable predicting an outcome variable. The term 'multivariable' is used in preference to 'multivariate' which is commonly also used to describe this situation. Classical statistical usage for the

term 'multivariate' is in describing analyses which are required to predict more than one outcome variable simultaneously, such as when one has a set of items purporting to measure a common dimension, for example, depression or anxiety, or when measurement of outcomes is repeated over time. We consider various models which arise, as a consequence of different outcome variables or study designs. As we shall see, these models share a common framework, the generalized linear model, which is a generalization of the simple regression model discussed earlier; models differ only where necessary to incorporate their different assumptions. We begin with models based on the normal distribution.

Normal theory regression

Having established that birthweight and maternal weight are associated, and having estimated the regression coefficient, we might be interested in further exploring the prediction of birthweight. We could perform the same analyses on a range of other variables, such as family income, tobacco, or alcohol consumption. In each case, a regression model provides us with a measure of the size of the effect (the regression coefficient, at a 95 per cent CI) and its statistical significance (p -value). In this way, we might identify a collection of predictors or 'risk factors'. It is likely that these relationships will themselves be related: consider the following example, now based on a sample of 500 births.

Regression of birthweight upon maternal pre-pregnancy weight yields:

$$\text{Birthweight (g)} = 2832 + 11.3 \times \text{maternal weight (kg)}.$$

Birthweight increases by 11.3 g per kg of maternal weight.

Regression of birthweight upon number of previous pregnancies yields:

$$\text{Birth weight (g)} = 3453 + 29.5 \times \text{number of previous pregnancies}.$$

Birth weight increases by 29.5 g per previous pregnancy.

But if a woman's weight increases with increasing number of pregnancies, then these two findings might be related; for example, does birthweight increase with increasing number of pregnancies

because of the increasing weight of the mother, or is the effect separate?

To examine this, we set up a multivariable linear model such as:

$$Y = \alpha + \beta_1 X_1 + \beta_2 X_2 + e$$

where β_1 and β_2 are regression coefficients indicating the dependence of Y upon variables X_1 and X_2 , X_1 being maternal weight and X_2 being the number of previous pregnancies. This model is fitted in the same way as before, to obtain:

Birth weight (g) = $2830 + 11.0 \times \text{maternal weight (kg)} + 16.9 \times \text{number of previous pregnancies}$.

We see that the maternal weight effect remains virtually the same, but the effect of number of previous pregnancies has about halved, and is no longer significant. To see why this has happened, we use our multivariate model to assess the effect of a difference in maternal weight of 1 kg on birthweight. Suppose a woman A has a pre-pregnancy weight of 50 kg and one previous pregnancy. Her baby's predicted birthweight (g) is $2830 + 11.0 \times 50 \text{ (kg)} + 16.9 \times 1$.

Suppose a second woman B has a pre-pregnancy weight of 49 kg and no previous pregnancies. The latter has an effect on birthweight, so B is not comparable to A. The prediction model can make A and B comparable in terms of pregnancy history, by setting B to have one previous pregnancy. The predicted birthweight for B's baby (if she had one previous pregnancy) is $2830 + 11.0 \times 49 \text{ (kg)} + 16.9 \times 1$.

Subtracting these two equations to obtain the difference in predicted birthweight for these two women, gives a predicted difference of 11.0 g, the regression coefficient for maternal weight in the multivariable model. Thus, the regression coefficient of 11.0 g represents the effect of an additional 1 kg of maternal weight, after controlling (or adjusting) for number of previous pregnancies.

Reciprocally, the regression coefficient for number of previous pregnancies reflects the association between birthweight and number of previous pregnancies, after adjusting for the effect of maternal weight in the multivariate model. As this effect has been much decreased to the point of non-significance, we would conclude that the significant effect we saw in the first, separate analysis was due to confounding by maternal weight.

A *confounding variable* is one that is associated with both the outcome variable and a predictor variable. In summary, a multivariable regression model yields estimates of the separate or 'adjusted' relationships between the outcome variable and the predictor variables.

Essentially, no new principles emerge when this process is extended to more predictors or risk factors. We obtain a series of estimated regression coefficients, and confidence limits for the parameters, and p -values, each reflecting the association between the outcome and the predictor, after adjusting for all other predictors included in the fitted model.

If an outcome variable is continuous, but the normal distribution for errors does not apply, the outcome variable can sometimes be transformed, so that the normal assumption is satisfied. Typical transformations include the log or square root transform, which can correct skewness. While these are useful statistical devices, they can sometimes make results more difficult to interpret.

Logistic regression

Logistic regression is used in similar situations to normal theory regression, but where the outcome variable is binary (e.g. dead/alive, having a specific disease or not) and we want to model the risk of this outcome (death, diseased) according to certain predictors or risk factors. The difference is that we use a transformation, called the *logit* transformation, to account for the binary nature of the variable. This is seen on the left hand side of the following formula:

$$\log(p) = \log\left(\frac{p}{(1-p)}\right) = \alpha + \beta_1 X_1 + \beta_2 X_2 + e$$

where \log is the logarithm function to base e , p is the predicted proportion of people with the outcome of interest, given particular values of the predictor variables X_1 and X_2 . Note that the left hand side is now modelling the $\log(\text{odds of outcome})$, where odds of outcome may be estimated by the number with the outcome, divided by the number without the outcome. The error distribution on the right hand side (e) is assumed to follow a binomial distribution, which is a probability distribution describing the number of times an outcome occurs, in a set number of individuals at risk. The regression coefficients β_1 and β_2 now need to be re-interpreted in the light of the transformation. When the model is fitted to data, and the regression coefficients back-transformed by exponentiating (taking anti-logs), we obtain odds ratios for the association between the outcome and the risk factor. The odds ratio is the odds of the outcome (defined earlier) within those who have the risk factor, divided by the odds of the outcome within those who do not have the risk factor. It is a widely used measure of association between a risk factor and an outcome. An odds ratio of one indicates no association between risk factor and outcome; odds ratios of greater than one or less than one indicate an increased or decreased risk of the outcome associated with the risk factor, respectively.

As an example, suppose we are interested in examining the predictors of overweight in adolescent girls, using data on 1823 14-year-old girls born into a cohort study (Najman et al. 2005). Of these we note that 466, or 26 per cent, are overweight at age 14, and also that being overweight at age 14 is associated with parental weight at the child's birth. A girl was more likely to be overweight at 14 if her mother was overweight at the start of the pregnancy (51 per cent of daughters of overweight mothers were overweight, compared to 21 per cent of non-overweight mothers). Calculating from first principles, the odds ratio for the association between mothers and daughters being overweight is $(0.51/(1 - 0.51))/(0.21/(1 - 0.21)) = 3.9$. A similar, but not quite so marked, result was noted for fathers' weight: 39 per cent of daughters of overweight fathers were overweight, compared to 21 per cent of daughters of non-overweight fathers. These data are displayed in Table 5.16.11.

In addition, girls who were overweight at age 14 had a mean birthweight of 3.4 kg, compared to 3.3 kg for those who were not. We could surmise (and can confirm by additional analyses) that the mother's pre-pregnant weight, the father's weight at the time of pregnancy, and the daughter's birthweight are likely to be positively associated, resulting in some confounding of their effects. In order to sort out the separate contributions of these three predictors we use a logistic regression model as follows. We would

Table 5.16.11 Association between maternal pre-pregnant overweight status and daughters' overweight status at age 14

Risk factor		N	Daughters overweight	Odds ratio (OR) for daughter overweight and risk factor (1 = reference category)
Mother overweight	No	1545	324 (21%)	Reference
	Yes	278	142 (51%)	3.9
Father overweight	No	1381	293 (21%)	Reference
	Yes	442	173 (39%)	2.4

Family and early life factors associated with changes in overweight status between ages 5 and 14 years: findings from the Mater University Study of Pregnancy and its outcomes. *International Journal of Obesity (London)*, 29(5):475–82.

Table 5.16.12 Logistic regression: predicting overweight in adolescent girls from maternal and paternal overweight status prior to pregnancy, and birthweight

Risk factor		Odds ratio (OR) for daughter overweight and risk factor (95% confidence intervals)		
		Unadjusted	Adjusted for other parental overweight	Adjusted for other parental weight and birthweight
Mother overweight	No	Reference	Reference	Reference
	Yes	3.9 (3.0–5.1)	3.5 (2.7–4.6)	3.4 (2.6–4.5)
Father overweight	No	Reference	Reference	Reference
	Yes	2.4 (1.9–3.0)	2.1 (1.6–2.6)	2.1 (1.6–2.6)
Birth weight	(kg)	1.4 (1.1–1.7)		1.2 (1.0–1.5)

Source: data from Mamun, A.A., Lawlor, D.A., O'Callaghan, M.J. et al. Family and early life factors associated with changes in overweight status between ages 5 and 14 years: findings from the Mater University Study of Pregnancy and its outcomes. *International Journal of Obesity (London)*, 29(5):475–82.

typically begin with a model which uses one risk factor at a time, then a multivariable model, or series of them which examines the effects of adjusting for other risk factors. As before, effects obtained from multivariable models are adjusted for all other variables (risk factors) in the model. When this is done for this example, we find the various effect estimates and 95 per cent CIs as shown in Table 5.16.12.

Our multivariable analyses (last two columns) show some reduction in effect estimates after adjustment, indicating that the effects of maternal and paternal overweight are largely separate effects. Adjusting for birthweight makes very little difference to the magnitude of parental effects. Notice that the effect of birthweight, as a continuous variable, is expressed differently to the categorical variables of parental overweight. The odds ratio for birthweight gives the increase in odds of the daughter being overweight at age 14, for a unit (1 kg) increase in birthweight, that is, a child who was 4 kg at birth is predicted to have 40 per cent increase in odds of being overweight at 14, compared to a child who was 3 kg at birth. This same relative increase applies when comparing a 3.5 kg child with a 2.5 kg child. When we include continuous variables in a logistic model we assume that the relative effect, per unit change in the variable, is constant. This is an assumption that should be checked.

Poisson regression

Poisson regression (named after the French mathematician who first described a probability distribution for count data) is used

when the outcome variable is a count variable (e.g. number of deaths over a period, or number of incident cases of disease). There are two differences, compared to normal theory regression. The first is that we apply a log transformation to our count data, and the second is that we (usually) have to incorporate an 'offset' variable which measures the period of time at risk, over which the events are accumulated. This model is expressed according to the following formula:

$$\begin{aligned} \log(\text{number of events}) &= \alpha + \beta_1 X_1 + \beta_2 X_2 + \log(\text{person-time at risk}) + e \\ \text{or, equivalently,} \\ \log(\text{event rate}) &= \alpha + \beta_1 X_1 + \beta_2 X_2 + e. \end{aligned}$$

The error distribution on the right hand side (e) is assumed to follow a Poisson distribution, which is a probability distribution describing a 'count' of a number of independent events. As for logistic regression, the regression coefficients β_1 and β_2 need to be re-interpreted in the light of the log transformation. When the model is fitted to data, and the regression coefficients back-transformed by exponentiating (taking anti-logs), we obtain rate ratios for the association between the outcome and the risk factor. The rate ratio in this context is the rate of the outcome (as a person-time rate) within those who have the risk factor, divided by the rate of the outcome within those who do not have the risk factor. Again a rate ratio of one indicates no association between risk

factor and outcome; rate ratios of greater than one or less than one indicate an increased or decreased risk of the outcome associated with the risk factor, respectively.

As an example, consider the results of a Poisson regression applied to examining risk factors for the occurrence of a particular form of skin cancer (squamous cell carcinoma (SCC)) in a cohort study. Because participants dropped out of the study at different stages throughout the 12-year period of follow-up, it was necessary to take account of each individual's person-time of follow-up. This leads to the offset variable described earlier. The outcome of this analysis was whether or not a participant had a new SCC lesion detected in the follow-up period. Note that an individual only appears once in the analysis. Subsequent new SCC lesions did not contribute. This is an important assumption of Poisson regression, that is, that the outcomes are independent of each other—it is likely that SCCs will tend to cluster within individuals, and therefore subsequent events within the same individual will not be independent. An alternative model (e.g. negative binomial regression) must be used if one wants to consider multiple events within an individual. Variables to be considered in a multivariable analysis for predicting SCC included sex, age, skin colour, history of skin cancer, and skin response to exposure to the sun. The results of this analysis are shown in Table 5.16.13.

The first column of rate ratios indicates the increase in risks associated with each risk factor (and their 95 per cent CIs), taken one at a time. The second column of rate ratios shows the increases in risks when each risk factor is adjusted for the effects of the others, and any associations among risk factors. We see that the general tendency is for rate ratios to reduce, after adjustment for confounding. Most notably, the RR associated with a previous history of skin cancer drops from 5.08 (3.55–7.20) to 2.50 (1.69–3.71) when adjusted for other risk factors; this is because factors (such as age, skin response to the sun) will be associated both with a past history and future risk of skin cancer. When these factors are taken into account, some of the effect of history

of skin cancer, as a single factor is reduced. Note also that the age effect appears modest—RR = 1.06 (1.05–1.08)—but one needs to take into account that this is the increase in risk, per year of age. Over a decade of age this translates to a cumulative rate ratio of 1.84 (1.64–2.23).

Cox proportional hazards regression

'The Cox proportional hazards model (Cox 1972) is a widely used method for multivariable analysis of survival data. It can be thought of as a combination of the Kaplan–Meier method which involves dividing the follow-up time into small intervals, and the Poisson regression model approach which formulates a model within each of these time periods.

Consider the WHAS data referred to in Fig. 5.16.6. Suppose our follow-up time is divided into intervals determined by the time points t_1, t_2, t_3 , etc. We imagine a regression model within each of these intervals (t_1, t_2) etc., which relates the probability of death within the interval to a risk factor, such as complications of a myocardial infarct. From such a model we can obtain an effect estimate (a relative risk of death in this case, associated with having complications) for that time interval. This relative risk would vary over time. However, we begin by making a simplifying assumption that the risk ratio (usually termed hazard ratio in this context) is constant over time—this is called the proportional hazards assumption.

We now consider a Poisson model', to cover the time period from t to $t+1$, as follows (Doi and Williams 2013).

$$\log(\text{event rate at time } t) = \alpha + \beta_1 X_1 + \beta_2 X_2 + e$$

Conceptually, this model is then fitted for each time period (with the constraint that the estimates β_1 and β_2 are, the same for each period). This occurs by a process called partial likelihood. The resultant parameter estimates then the log of the hazard ratio.

Table 5.16.13 Comparison of unadjusted and multivariable Poisson regression for risk factors for SCC: rate ratios

Risk factor		Rate ratios (RR) for incidence of SCC (95% confidence intervals)	
		Unadjusted	Multivariable analysis
Sex	Female	Reference	Reference
	Male	1.53 (2.17–5.72)	1.39 (0.98–1.99)
Age	Years	1.08 (1.06–1.10)	1.06 (1.05–1.08)
Skin colour	Olive	Reference	Reference
	Medium	1.33 (0.52–3.40)	1.22 (0.47–3.14)
	Fair	2.11 (0.86–5.21)	1.60 (0.63–4.07)
History of skin cancer	No	Reference	Reference
	Yes	5.08 (3.55–7.20)	2.50 (1.69–3.71)
Skin response to sun	Tans	Reference	Reference
	Burns, then tans	1.13 (0.59–2.20)	1.45 (0.74–2.86)
	Burns, never tans	2.33 (1.17–4.62)	2.12 (1.02–4.39)

Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al., Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

The usual form of the model expresses the ‘intercept’ as a log of a ‘baseline hazard’, this being the predicted death rate for the reference category of the predictor variable:

$$\begin{aligned} & \log(\text{event rate at time } t) \\ &= \log(\text{event rate at time } t \text{ for} \\ & \quad \text{reference categories for } X_1 \text{ and } X_2) \\ & \quad + \beta_1 X_1 + \beta_2 X_2 + e. \end{aligned}$$

Thus the hazard ratios β_1 and β_2 give the multipliers of the baseline hazard associated with being in particular risk groups. You can see that the hazard ratios ‘multiply’, since the above model, after exponentiating both sides becomes:

$$\text{Event rate at time } t = \text{event rate at time } t \text{ for reference categories for } X_1 \text{ and } X_2 \times \beta_1 X_1 \times \beta_2 X_2.$$

When we fit a Cox model to the WHAS data, using the predictors of patient’s sex, age (years), and presence of complications, we find the following, as shown in Table 5.16.14.

The ‘unadjusted’ hazard ratios represent separate models, one at a time. The multivariable analysis gives hazard ratios which are mutually adjusted for other variables in the model. Thus we see the sex effect reduces when age and complications are taken into account. The magnitude of the complications effect reduces but remains quite strong.

The proportional hazards assumption and time-dependent variables

As noted earlier, the formulation of the above model assumes a constant hazard ratio. We can formally test this assumption and alter the model to accommodate some variation in the hazard ratio. We can also include time-dependent risk factors. For example if we want to include alcohol intake as a risk factor, we could include alcohol intake measured at baseline (time constant) or at any point in time, when it might change (time-dependent). While the process for doing this is a little complicated, no new concepts emerge in terms of interpreting results.

Variations and extensions to other probability models

Logistic regression has been extended to the situation where one has a categorical outcome with more than two outcomes. This

Table 5.16.14 Cox regression for mortality after a myocardial infarct by patient age at MI, sex and presence/absence of CHF complications

Risk factor		Hazard ratios (RR) for death (95% confidence intervals)	
		Unadjusted	Multivariable analysis
Sex	Female	Reference	Reference
	Male	1.46 (1.12–1.92)	0.86 (0.65–1.13)
Age	Years	1.07 (1.06–1.08)	1.06 (1.05–1.08)
Complications	No	Reference	Reference
	Yes	3.31 (2.53–4.34)	2.41 (1.82–3.19)

Source: data from Tonne, C., Schwartz, J., Mittleman, M., Melly, S., Suh, H., and Goldberg, R. (2005). Long-term survival after acute myocardial infarction is lower in more deprived neighborhoods. *Circulation*, 111, 3063–70.

is known as a multinomial (as opposed to a binomial) model and leads to *multinomial regression*. A standard multinomial model will require more than just a single odds ratio parameter associated with each risk factor level, since now there are more outcome levels to deal with. For example, suppose an outcome variable has three levels (no disease, moderate level severity disease, severe disease), and we are evaluating a binary risk factor (history of tobacco use, no history). A multinomial model will involve an odds ratio quantifying the increased risk associated with smoking for moderate-level severity disease, and another quantifying the increased risk for severe disease. If the outcome variable is an ordinal variable (such as in the current example), then the multinomial model can be simplified by assuming that the odds ratios associated with moving from no disease to moderate-level severity disease, and from moderate disease to severe disease are the same. This is referred to as *cumulative logit regression*. The assumption of a common odds ratio is called a proportional odds assumption and should be checked for validity as it is quite a strong assumption. It is sometimes considered that a disadvantage of logistic regression is that it results in odds ratios, which are often not good measures of relative risks, particularly in dealing with outcomes which occur commonly. *Log-binomial regression* has been proposed to deal with this situation, since it assumes a binomial distribution of errors (as does logistic regression) but the use of a log rather than logit distribution results in estimated effects which are interpreted as risk ratios. However, fitting these models can sometimes be technically problematic.

As mentioned earlier, Poisson regression assumes that the outcomes of interest are independent. There are many instances when this is not the case. In the SCC example given earlier, individuals will probably have a propensity to develop SCC which is not fully explained by the risk factors we include in a model, leading to a failure of the assumption of independence. In modelling the occurrence of episodes of an infectious disease, this will also be a problem—while we can ‘explain’ some of the aggregation of episodes within individuals by our predictor variables (nutritional status, environmental exposure, etc.), we are unlikely to explain this completely, as unmeasured and unknown factors will affect the risk of an episode. One of the most common alternatives to use is *negative-binomial regression* which posits a somewhat more complex mechanism for development of an episode, that is that each individual has a particular propensity for the outcome (e.g. a skin cancer), and that given this propensity, an individual’s number of episodes will have a Poisson distribution. Once this more complex process is taken into account, the results of a negative-binomial distribution are very similar to those of a Poisson distribution, that is, one obtains rate ratios for episodes of the outcome of interest. Other alternatives are also used, which include *zero-inflated regression* models. These are based on models such as the Poisson or negative-binomial but particularly assume that there are more values of zero counts (numbers of episodes) than would be predicted by those models. This would be particularly appropriate in the case of a vector-borne disease, for example, where the population may include a large subpopulation who have no exposure to the relevant vector, and a smaller subpopulation who have varying, but non-zero, exposure.

Study designs which have a hierarchical nature often use *random effect regression* models. These may involve different types of probability models, but have the defining feature that they include

factors (covariables) which are considered themselves to have distributions. For example, one may design a study to examine the relationship between air pollution and child health. A number of sites are chosen which are close to air pollution monitoring stations, and a sample of schools is selected within a defined radius of the monitoring sites. Children are chosen from each school and their lung function measured. In this case a regression model with lung function as the outcome would be appropriate, and the primary risk factor would be the air pollution level, with perhaps other covariables (socioeconomic status, age, sex, etc.) also used in a multivariable model. However, variation among schools needs also to be taken into account. Given that we had taken a sample of schools, we would regard this effect as random, in the sense that we want to regard the study schools as representative of all schools. This contrasts with the more usual ‘fixed’ effects, such as for smoking status where we have levels of non-smoking or smoking and there is no sense in which we have a sample of levels of smoking. A consequence of a random effects regression model is that we can allow for effects (such as the mean lung function or the regression coefficient linking lung function and air pollution) to vary by school. Our model then examines the variability of these effects and estimates a mean across schools. Thus one has within-school effects and between-school effects.

The multivariable models so far considered have the common property that they either consider individual records to be independent, or, as in the negative-binomial or the random effects model, incorporate non-independence into the probability model itself. Non-independences occur in many study designs. These include repeated measures designs, hierarchical designs, or spatial designs. Regression models applied to such designs incorporate a non-independence correlation structure which allows the correlations between measures within the same individuals over time, or within the same subpopulation, or the same spatial unit, to be estimated and taken into account. Depending on the software used, a variety of options is available for this structure, such as a constant correlation, an exponentially decaying correlation over time or space, and others. Complex designs are often fitted using the method of *generalized estimating equations* (GEEs), which is an extremely flexible approach to fitting models, and has an added advantage of coping somewhat better with missing data than classical fitting approaches.

Generalized additive regression models (GAMs) have been used particularly to explore non-linearity in effects. A simple regression model assumes, for example, that the relationship between a continuous outcome variable (birthweight) and a predictor (maternal weight) is linear—the increase in birthweight per unit of maternal weight is constant over the range of maternal weight. This is a strong assumption and will often need to be explored. A GAM is constructed in a very similar fashion to a generalized linear model except that one may specify a predictor as a collection of curvilinear functions fitted over various subranges of the

predictor variable. The complexity of the non-linearity may be specified. This is a very sensitive and flexible approach to exploring curvilinearity of effects, or in the case of a confounding variable which has non-linear effects, ensuring minimal residual confounding.

Summary

Modern statistics and software offer a wide array of approaches to statistical analyses. The key to appropriate and efficient analysis lies in clarity around the study design and the questions to be answered, thorough preliminary analyses of the data available and selection of the appropriate techniques to be used, and a critical approach to presentation and interpretation of results. Common errors include applying techniques that are not appropriate to variable types or their distributions, ignoring design features (such as repeated or hierarchical sampling), and misinterpretation of computer output. Unfortunately, the availability of statistical software that can perform sophisticated analyses is likely to make these errors more frequent, rather than the opposite. There is little substitute for consulting a qualified statistician, particularly with complex study designs.

Measuring the health of populations: the Global Burden of Disease study methods

Theo Vos and Christopher J. L. Murray

Introduction to measuring the health of populations

Over the last two decades, the global health landscape has undergone rapid transformation. People around the world are living longer than ever before, and populations are getting older. Many countries have made remarkable progress in preventing child deaths. As a result, disease burden is increasingly defined by disability as opposed to being dominated by premature mortality. The leading causes of death and disability are shifting from communicable diseases in children to non-communicable diseases in adults. These global trends differ across regions. Notably, in sub-Saharan Africa, communicable, maternal, and newborn diseases and nutritional deficiencies continue to dominate. While low- and middle-income countries are tackling this ‘unfinished agenda’ of largely poverty-related diseases, increasingly, they also need to prepare their health services for a growing burden of non-communicable diseases and injuries, which some have called the ‘double burden’ or ‘triple burden’ (Bradshaw et al. 2003; Marshall 2004; Boutayeb 2006). In high-income countries, health budgets are steadily increasing relative to gross domestic product due to ageing of the population, an ever-expanding array of medical technologies, and greater demands of consumers for healthcare services (Smith et al. 2009). For governments and other healthcare providers to be able to respond to these challenges, high-quality comparable data on the size and trends in mortality and morbidity are essential. The word ‘comparable’ is of paramount importance. Commercial and professional interests often lead to implausible claims of the number of deaths or cases affected by a particular disease. The only way to deal with these exaggerated claims is to make a comprehensive assessment of the health of each population by ensuring that all deaths by cause add up to the total number of deaths and a similar rigor applied to classifying cases of disease. The two more prominent examples of independent assessments of population health statistics are the Child Epidemiology Reference Group of the World Health Organization (WHO) which has made global estimates of

childhood deaths (Black et al. 2010) and the successive iterations of the Global Burden of Disease study (GBD—a full list of abbreviations is given in Table 5.17.1) (Murray and Lopez 1996; Mathers et al. 2008; Lozano et al. 2012; Murray et al. 2012a). The latter endeavour is the only one to estimate health loss across the age spectrum and for all diseases and injuries. After the initial GBD assessment for 1990, updates until 2008 have largely continued to use the same methods with piecemeal improvements. In 2007, the Bill & Melinda Gates Foundation funded the Global Burden of Diseases, Injuries, and Risk Factors Study 2010 (GBD 2010) which endeavoured to re-think methods and assumptions underlying population health measurement while making use of the vastly improved health data and computational resources. This chapter describes the methods underlying the GBD 2010 study.

About GBD 2010

The GBD approach is a systematic, scientific effort to quantify the comparative magnitude of health loss due to diseases, injuries, and risk factors by age, sex, and geography for specific points in time. GBD 2010 was published in a series of papers in *The Lancet* in December 2012. The information is made available as a global public good that will be useful for informing the design of health systems and the creation of public health policy. GBD 2010 estimated premature death and disability from 291 diseases and injuries, 1160 sequelae (direct consequences of disease and injury), and 67 risk factors for 20 age groups and both sexes in 1990, 2005, and 2010. The study produced estimates for 187 countries and 21 regions and generated nearly 1 billion estimates of health outcomes.

GBD 2010 was a collaborative effort among 488 researchers from 50 countries and 303 institutions. The Institute for Health Metrics and Evaluation (IHME) acted as the coordinating centre for the study. The collaboration strengthened both the data-gathering effort and the quantitative analysis by bringing together some of the foremost minds from a wide range of disciplines. The intention is to build on this collaboration by enlarging the network in

Table 5.17.1 Abbreviations

CODEm	Cause of death ensemble model
DALY	Disability-adjusted life year
DFLE	Disability-free life expectancy
DW	Disability weight
GBD	Global Burden of Disease
HALE	Health-adjusted life expectancy or health life expectancy
ICD	International Classification of Diseases and Related Health Problems
IHME	Institute for Health Metrics and Evaluation
${}_5q_0$	Probability of dying before 5th birthday
${}_{45}q_{15}$	Probability of dying between 15th and 60th birthday
QALY	Quality-adjusted life year
UNAIDS	Joint United Nations Programme on HIV/AIDS
VA	Verbal autopsy
WHO	World Health Organization
YLD	Years lived with disability
YLL	Years of life lost

years to come. IHME and its collaborators will expand the list of diseases, injuries, and risk factors included in GBD and routinely update the GBD estimates. Continual updates will ensure that the international community can have access to high-quality estimates in the timeliest fashion. Through sound measurement, it will provide the foundational evidence that will lead to improved population health.

Value choices and population health metrics

Several metrics that combine mortality and morbidity are in use. They all have in common that health loss or health gain is measured in units of time. There are two classes of population health measures: health expectancies and health gap measures. Health expectancies extend the concept of life expectancy, a composite measure of age-specific mortality rates in a given year in a population, and adjust years in a life table for loss of health from non-fatal conditions. Demographers calculate life expectancy in a life table by applying the currently prevailing mortality rates in a population to a hypothetical birth cohort. In each row of the life table deaths and survivors of the birth cohort are tracked at successive age groups until a top age category (e.g. 80+ or 100+) in which everyone is assumed to die. In each age group the average number of years lived is calculated and the sum of years lived over all ages divided by the initial size of the assumed birth cohort is the average life expectancy. A common interpretation of life expectancy is ‘the average number of years a child born today can expect to live’. Of course, this interpretation only holds if the currently prevailing mortality rates at each age would continue to apply for the total life span of the birth cohort. In reality, mortality rates are changing considerably over time. As mortality rates are declining at almost all ages in most countries, the true life expectancy in a

population is higher than the figures that are frequently used in health statistics. However, it is a popular and frequently used statistic because it is an easy way to summarize in one number a lot of detailed information on mortality rates by age and because users have an intuitive understanding how to interpret a life expectancy measure (even if that interpretation is not quite right).

Health expectancies are an adaptation of life expectancy taking into account that not all years of remaining life expectancy are lived in good health. The coarsest version of health expectancy is the disability-free life expectancy (DFLE) which classifies disability in a dichotomous way: those above the threshold contribute no time to DFLE and those below contribute a full year to the measure (Murray 2002). Health-adjusted life expectancy (HALE), also sometimes referred to as healthy life expectancy, grades the severity of disability across several categories or the full spectrum and adjusts time lived at each age in a life table by the severity-weighted prevalence of disability. The attractions of health expectancies are that they capture health of a population in a single number and that the concept is relatively easy to explain to policymakers. Its main uses are ranking lists by country or subpopulations within a country, and tracking of change over time for the same population. The downside of health expectancies is that it is not easy to attribute a population’s health to underlying diseases, injuries, or risks.

The disability-adjusted life year (DALY) is a health gap measure that was created to allow measurement of a population’s health with the ability to express the contribution of diseases, injuries, and risks as a proportion of the total burden of disease. It is called a health gap measure as it quantifies loss of health from mortality and morbidity in a population against a stated ideal that ‘everyone should live until a ripe old age, free of disease’. A number of social value choices are incorporated into the DALY, all of which have been reconsidered by a panel of ethicists and philosophers for GBD 2010 (Murray et al. 2012b).

The first inevitable choice in constructing a health gap measure concerns the choice of the standard for length of life. In earlier versions of GBD, a standard life table was chosen that mirrored life expectancy of Japanese women in the early 1990s. This was Coale and Demeny’s West level 26 female model life table with a life expectancy at birth of 82.5 years (Coale and Demeny 1966). A choice was made to set a slightly lower standard for men, postulating a biological difference in life expectancy between men and women. As there was no male model life table in the Coale and Demeny series that came close to the chosen female life table, the West level 25 female model life table with life expectancy at birth of 80 years was chosen for men. Use of a standard life table essentially is a weighting for age at death: infant deaths are considered equivalent to a loss of the number of years of life expectancy at birth; a death at age 20 is equivalent to the loss of the remaining life expectancy at that age. It also follows that even deaths at the oldest age groups still account for some years of life lost. The panel of ethicists and philosophers advised that there was no clear rationale for a difference between males and females and that it would be fitting to update the standard to achievable levels of life expectancy in 2010. A choice was made to create a new standard life table consisting of the lowest observed mortality rates in any age group in any population greater than 5 million. This is a standard life table with life expectancy at birth of 86.0 years. The full list of life expectancy at each age from the standard life table

can be found in the web appendix to one of the GBD 2010 papers published in *The Lancet* (Murray et al. 2012a).

A second choice is whether to apply the same standard life table to all populations and over time. From a principle of wishing to compare 'like with like' and for the sake of making meaningful comparisons of changes in health status of populations over time, GBD uses a single model life table to measure years of life lost, regardless of whether the death occurred in a population currently experiencing high or low mortality rates.

A third choice that has to be made in a summary measure like the DALY is how to value health loss from non-fatal conditions relative to the loss of health from deaths. The previous two choices determined how counts of death are translated into a number of years of life lost. To translate non-fatal health loss in a population into a comparable time measure of 'lost healthy years' a severity weighting for each disease or consequence of disease and injury is needed. The original GBD study in the 1990s derived these 'disability weights' (DWs) from a panel of international health experts who valued 22 tracer conditions with person trade-off methods. Subsequently, they were asked to interpolate all remaining health states by indicating a distribution across seven classes of severity after binning the valuations for the 22 tracer conditions (Murray and Lopez 1996). DWs ranged from a low of 0.005 for mild anaemia and a high of 0.85 for a number of severe congenital anomalies. Since then, national burden of disease studies (Melse et al. 2000; Begg et al. 2008) have continued to use these DWs but supplemented them with a new set of DWs developed for the Dutch burden of disease study (Stouthard et al. 2000), as well as a number of ad hoc derivations of DWs for new conditions. As this had led to a lack of consistency between DWs and because there had been criticism of depending on the values of a small panel of health experts, for GBD 2010 population surveys were conducted in Peru, Indonesia, Bangladesh, Tanzania, and the United States, as well as an open-access Internet survey. More than 30,000 respondents took part from 167 countries. To minimize the cognitive burden a simplified method of pair-wise comparisons was adopted. Each time, a respondent was asked to decide between two health states 'who is the healthier?'. The health states were described in short lay descriptions capturing the essential domains of loss of function in fewer than 35 words, as pilot testing indicated this was the maximum of information respondents were able to absorb. Valuations were obtained for a parsimonious set of 220 health states covering all 1160 sequelae. In addition, respondents to the Internet survey were asked to answer a small number of population health equivalence questions to anchor the values from the pair-wise comparison on a 0–1 scale, where 0 represents no health loss and 1 represents health loss equivalent to being dead. All DWs were estimated with an uncertainty interval. The least severe DW of 0.005 was for mild hearing loss and a mild infectious disease episode while the worst DW of 0.756 was given to the acute, psychotic phase of schizophrenia. Further methods and details of all lay descriptions and DWs can be found in Salomon et al. (2012a).

Two other choices that had been used in previous GBD studies, discounting and age-weighting, were rejected by the panel of ethicists and philosophers. Both these choices had been subject to criticism in the academic literature (Anand and Hanson 1997; Tsuchiya 2001; Arnesen and Kapiriri 2004) but also were difficult to explain to policymakers. With discounting a future stream of lost health, greatest value is given to loss of health in the year

of interest while years into the future gets valued less and less. Previous GBD studies used an instantaneous discount rate of 3 per cent which meant that a female infant death with a standard life expectancy of 82.5 years would translate into 30.5 years of life lost. Age-weighting was a further complication incorporated into the DALY of previous GBD studies. The age-weighting function gives less value to health loss at young and older ages and greater value to health loss in young adults arguing that the latter have a social duty to look after the young and the old.

A further general choice is whether to generate estimates of non-fatal health loss from incident or prevalent cases. Previous GBD studies have used an incidence approach arguing that it fits better with the measurement of lost years from deaths and that it would suit policymaking about prevention, as the future stream of health lost in an incident case of disease reflects the potential health gain from prevention (Murray and Lopez 1996). However, it was difficult to explain to policymakers that the burden of disease in a particular year was not reflecting the health loss from current cases of disease. The most important consideration to adopt a prevalence approach to non-fatal health loss measurement in GBD 2010 was that it would have been computationally nigh impossible to correct for co-morbidity with an incidence approach, as it would have to deal with a large combination of lost health streams of different durations. A corollary of choosing a prevalence approach is also that by definition you cannot apply discounting, but that was a decision already made.

This was a long introduction about the metrics used in burden of disease and how key assumptions have changed over time. It is important to point out that any change in these value choices means using a different metric that is no longer comparable to another. For that reason, in GBD 2010 estimates were explicitly re-estimated for 1990 to avoid anyone making comparisons with the original GBD 1990 estimates. While not necessarily pertinent to this chapter, it seems wise to explain the difference between DALYs used in burden of disease and DALYs that are used in economic evaluations. In economic evaluations DALYs are no longer defined as a health gap measure quantified against the standard life expectancy. Instead, the mortality rates are used that apply to the population of interest for which the cost-effectiveness of one or more health interventions is being evaluated. Similar to the use of quality-adjusted life years (QALYs), economic evaluation models using DALYs compare the future health consequences between a population getting a particular health intervention and a population receiving an alternative (e.g. 'current practice' or no intervention). In both arms of such models the amount of time lived is recorded and time lived with non-fatal health outcomes is multiplied by one minus a DW in DALYs and by a utility weight in QALYs. The difference between disability-adjusted or quality-adjusted time lived between the two arms of the model determines the health gain (or loss) attributed to the health intervention of interest. A list of key terms is found in Box 5.17.1.

Estimation principles

The GBD cause list is a set of mutually exclusive and collectively exhaustive categories. The 291 causes included in GBD 2010 were chosen based on considerations of their relevance to global health policymaking and/or the size of their expected contribution to mortality and/or morbidity burden.

Box 5.17.1 Key terms

Years of life lost (YLLs): years of life lost due to premature mortality.

Years lived with disability (YLDs): years of life lived with any short-term or long-term health loss.

Disability-adjusted life years (DALYs): the sum of YLLs and YLDs. DALYs are also defined as years of healthy life lost.

Healthy life expectancy, or health-adjusted life expectancy (HALE): the number of years that a person at a given age can expect to live in good health if current rates of mortality and disability would remain constant.

Sequelae: consequences of diseases and injuries.

Health states: groupings of sequelae that reflect key differences in symptoms and functioning.

Disability weights: number on a scale from 0 to 1 that represents the severity of health loss associated with a health state.

Uncertainty interval: a range of values that is likely to include the correct estimate of health loss for a given cause.

All quantities of interest are estimated arguing that an uncertain estimate even when data are sparse or not available is preferable to no estimate. No estimate is often taken to mean no burden from that condition.

To convey to users the strength of the evidence for each quantity, uncertainty distributions for each quantity are reported in various metrics of uncertainty such as 95 per cent uncertainty intervals.

An important component of the analytical work on GBD is to ensure that the set of results are internally consistent. The sum of cause-specific mortality must equal all-cause mortality: ‘you only die once’. Deaths are assigned following International Classification of Diseases and Related Health Problems (ICD) rules on underlying cause. The sum of cause-specific estimates of impairments such as blindness and anaemia must equal estimates of all-cause blindness and anaemia. Where conditions are in equilibrium, incidence, prevalence, remission, and duration must be internally consistent.

Burden of disease estimation should be seen as an iterative process. New data and methodological innovation will lead to revision of estimates. Revisions should re-estimate the entire time series so that results are always available over time using consistent data and methods.

Data synthesis

The emphasis in the GBD 2010 is on systematically identifying all published and unpublished data sources. Published literature is a good source for some conditions such as epilepsy. For many others, national data systems such as vital registration, hospital discharges, national surveys, and surveillance data are equally important sources. By starting with the universe of all measurements, we can avoid publication or selection bias where different groups pick and choose between data sources.

Making use of all available data requires careful consideration of non-sampling error due to variation in case definition, diagnostic technology, study design, training of data collectors, recall periods (1 month, 12 months, lifetime), etc. For example, review

of diabetes prevalence studies found 18 different case definitions in use and review of myocardial infarction data showed marked differences in rates using heart-related serum creatine kinase fraction or troponin tests. Across studies or measurements, sampling error is a much smaller contributor to observed variance than these sources of non-sampling error. The GBD approach is to identify and correct for bias.

Key areas in cause of death data concern mapping across variants of the ICD, redistribution of ill-defined or ‘garbage’ codes, and validity of verbal autopsy (VA) diagnoses (attribution of cause of death based on interviews with relatives of a deceased). For epidemiological data, statistical methods are used to quantify the relationship between different types of measurement such as variations in case definitions, diagnostic technologies, or recall periods. Setting a ‘desired’ reference measurement definition allows adjustments of all available data (‘crosswalks’) into comparable units, definitions, or categories. Where possible, uncertainty in these mappings is propagated into the uncertainty interval for the measurement. Some measurements may have to be excluded because they cannot be made comparable to the rest of the measurements or have fundamental problems of validity. For instance, measures of lifetime prevalence were rejected as invalid measures of disease occurrence due to recall bias. A few exceptions to this rule were made for conditions where exclusion of such estimates would leave little other information for making estimates.

After adjusting the data into comparable units, appropriate statistical methods are used that are designed to handle both sampling and non-sampling error. Covariates are added to the models to improve predictions where data are sparse by borrowing strength across time or geography. All estimates in GBD are generated with 1000 draws reflecting uncertainty from sampling error, non-sampling error, methods of correcting data, and where possible, model specification. Ideally, the validity of the data synthesis approach is determined using out-of-sample predictive validity. This has been fully implemented for mortality and causes of death but not for the synthesis of data on disease sequelae. Computational limitations and sparse data have so far limited the extent to which formal out-of-sample predictive validity can be evaluated for disease sequelae.

The analytical steps of GBD

The GBD approach contains 22 distinct components, as outlined in Fig. 5.17.1. The components of GBD are interconnected. For example, when new data are incorporated into the age-specific mortality rates analysis (components 2 and 3), other dependent components must also be updated, such as rescaling deaths for each cause (component 9), healthy life expectancy, or HALE (component 17), YLLs (component 18a), and estimation of YLLs attributable to each risk factor (component 22a). A brief description of these key components follows. More detailed descriptions of each component are included in published articles (Black et al. 2010; Lim et al. 2012; Lozano et al. 2012; Murray et al. 2012a, 2012b; Salomon et al. 2012a, 2012b; Vos et al. 2012).

1. Covariates

Where data are sparse, extensive use is made of a database of covariates that guide statistical methods on borrowing strength across time or geography. The more than 200 covariates cover

Fig. 5.17.1 The 22 components of the Global Burden of Disease study.

socioeconomic factors (e.g. gross domestic product), demography (e.g. population density, total fertility rate), behaviours (e.g. mean consumption of alcohol, tobacco, and a range of foods), and health system characteristics (vaccination coverage or a composite measure of health systems access). Essential is that values are available for all populations and years of analysis. The information largely comes from international databases, national censuses, and surveys. Where information is missing for a time period or particular population, imputation techniques are used to fill in the gaps.

2. Estimating mortality in children under 5

Sources of under-5 mortality data include vital and sample registration systems as well as surveys and censuses that ask mothers about live births and deaths of their children. All available data are processed to address biases and estimate the probability of death between ages 0 and 5 (φ_0) using Gaussian process regression.

3. Estimating adult mortality

Sources of adult mortality include vital and sample registration systems as well as surveys and censuses that ask about deaths among siblings. Similar methods to those for childhood deaths are used to estimate the probability of dying between ages 15 and 60 ($_{45}q_{15}$).

4. Life tables

The estimates of ${}_5q_0$ and ${}_{45}q_{15}$ are entered into a model life table system to determine age-specific mortality rates by sex for each country between 1970 and 2010 with life expectancy at birth estimates and counts of death by age, sex, country, and year as outputs.

5. Cause of death data sources

Information on causes of death comes primarily from vital registration systems and VA studies. VA is a means of ascertaining the cause of death in populations with incomplete vital registration systems. With a structured questionnaire, interviewers ask relatives about the signs and symptoms of a recently deceased individual. Validation studies suggest that VA performs reasonably well for many causes of death (Lozano et al. 2011). For selected causes, additional sources such as police records for homicides and road traffic accidents, surveillance systems for maternal mortality and cancer registries provide further information.

6. Data correction, mapping, and redistributions

A first task to make cause of death data comparable is the mapping across various revisions and national variants of the ICD. Algorithms have also been developed to deal with the problem of

ill-defined coding in vital registration and VA data where deaths are assigned to unknown causes, intermediate causes, or immediate causes of death rather than the underlying cause of death. For comparisons between countries and over time it is undesirable to have varying numbers of death in such 'garbage' code categories. The GBD approach is to reassign such deaths to more specific causes. The allocation of these garbage codes across target causes is done on the basis of published scientific literature, expert judgement, or statistical analysis. In some cases, deaths in garbage codes are reassigned proportionately across all causes. Full details can be found in the web appendix to the GBD paper on causes of death by Lozano et al. (2012).

7. Cause of death database

The GBD 2010 cause of death database contains 2798 site-years of vital registration data from 130 countries and 486 site-years of VA data across 66 countries, of which 10 per cent were nationally representative. For the estimation of mortality from cancer, 2715 site-years of cancer registry incidence data across 93 countries were included. From registries that also track cancer mortality, mortality-to-incidence ratios were derived. The log of the mortality-to-incidence ratios for each type of cancer was modelled as a function of national income per capita with random effects for country, year, and age. The ratios were then applied to the incidence figures and the resulting cancer death estimates added to the cause of death database. For injuries, information on the proportions of deaths due to injuries was added from 32 site-years of burial and mortuary data in 11 African countries and from 21 site-years of data on deaths in health facilities. Multiple demographic and health surveys, other surveys, and censuses provided data on the fraction of deaths in the reproductive age groups that are pregnancy-related. Sibling history data from 1609 survey years covering 61 countries were identified. Another eight countries had nationally representative maternal mortality surveillance systems.

8. Estimating causes of death

GBD 2010 used a new statistical approach, named CODEm (Cause of Death Ensemble model), to determine the number of deaths from each cause by age, sex, country, and year. Ensemble modelling was made famous by the recipients of the Netflix Prize, BellKor's Pragmatic Chaos, in 2009, who engineered the best algorithm to predict how much a person would like a film, taking into account their past movie preferences.

The basis of CODEm is that the analyst takes no firm position on what the best statistical method and choice of predictive covariates are but rather tests a large range of plausible statistical models and determines which single model or combination of models performs best. Four families of statistical models are used: mixed effects linear and spatial-temporal Gaussian process regression models of either the log of the death rate or the logit of the cause fraction. These four families of statistical models are run with multiple combinations of covariates. Based on published studies, plausible relationships between covariates and each cause are identified and tested. All models where the sign on the coefficient for a covariate is in the direction expected based on the literature and the coefficient is statistically significant are retained.

Next, the performance of single models and blends of various models, so-called ensembles, is evaluated using out-of-sample

predictive validity tests. This is done by running the models on 70 per cent of the data and comparing predictions for the remaining data withheld from the model-building exercise with the actual observed data. Tests of out-of-sample performance include the root-mean-squared error of the log of the cause-specific death rate, the direction of the trend in the prediction compared to the data, and the validity of the 95 per cent uncertainty interval. The best performing model or ensemble is selected on the basis of out-of-sample predictive validity.

Typically for each cause of death, several hundred single models were run and ensembles created of five to 20 best-performing individual models, but for some causes almost 100 models contributed to the final ensemble.

CODEm was not used for a number of conditions, including infectious diseases such as HIV/AIDS, measles, whooping cough, and congenital syphilis, which are known to be subject to considerable misclassification bias. Instead, natural history models were created based on incidence, prevalence, and case-fatality rates. Estimates of HIV/AIDS deaths were taken directly from UNAIDS. For another 27 causes with very low numbers of death for which stable ensemble models could not be created, negative binomial models were run with a choice of plausible covariates. Information on deaths due to conflict and natural disasters from international databases was used to incorporate sudden peaks in mortality from these two causes.

9. Rescaling deaths to equal all-cause mortality

The number of deaths from all causes in a sex, age, country, and year category are scaled to ensure their sum equals the total number of deaths estimated in the GBD demographic analysis of steps 2 to 4.

10. Systematic review of the epidemiology of disease sequelae

A large effort by 44 expert groups and the core research team went into the systematic review of published and unpublished data on the prevalence, incidence, remission, mortality risk, and duration of 289 diseases and injuries and their 1160 sequelae. The systematic reviews were supplemented with analyses of household survey data, antenatal clinic surveillance, reportable disease notifications, disease registries, hospital admissions data, outpatient visit data, population-based cancer registries, active screening data, and other administrative data. As with data on causes of death, a considerable effort has gone into documenting factors that influence the quality and comparability of all data points, such as different case definitions, diagnostic technologies, and sampling strategies (Vos et al. 2012).

11. Estimating disease sequelae prevalence by Bayesian meta-regression

For the task of developing estimates for disease prevalence by age, sex, year, and country, a Bayesian meta-regression tool was specifically developed for GBD: DisMod-MR. This tool was designed to process data presented with a wide variety of age intervals; to predict values for countries and regions with sparse data; to correct data from studies with different case definitions, diagnostic technology, or sampling strategies; and to ensure internal consistency

between related epidemiological parameters such as incidence, prevalence, excess mortality, and duration. DisMod-MR estimates a generalized negative binomial model for all epidemiological data. The model includes the following: covariates that predict variation in true rates; covariates that predict variation across studies because of measurement bias; super-region, region, and country random intercepts; and age-specific fixed effects. When appropriate, the rates were assumed to have been constant over time, which allowed data for incidence, prevalence, excess mortality, and cause-specific mortality to inform prevalence estimates. The differential equations governing the relation between the parameters of incidence, remission, mortality, prevalence, and duration are well characterized (Barendregt et al. 2003). More detail is provided elsewhere on the development and application of DisMod-MR (Vos et al. 2012).

An additional part of the analysis has been to try and deal with selection bias intrinsic to some data sources, such as hospital discharges where access to care influences the number of discharges in a population or antenatal clinic data on HIV prevalence. More elaborate natural history models were used for some causes, such as HIV and hepatitis, which require multiple stages of disease progression to be accounted for.

12. Cross-validation of impairment levels

There are no data sources we can use to set all-cause disability in a population similar to the all-cause mortality rates from demographic data sources that determine the ‘envelope’ of deaths. However, there are a number of impairments for which there are data collections of the overall prevalence in a population. In GBD 2010 this was the case for vision loss, hearing loss, anaemia, infertility, heart failure, intellectual disability, and epileptic seizures. In these cases, the quality and extent of data on the overall impairment level was considered stronger than the disease-specific estimates of the same impairments.

13. External cause and nature of injury analysis

Injuries are classified in the cause list according to the external cause such as a road injury, animal bite, or drowning, whereas the disability from injury is determined by the nature of injury such as brain trauma, hip fracture, or spinal cord lesion. The injury analysis was carried out in six steps. First, household survey and hospital discharge data were analysed using DisMod-MR to generate estimates of incidence for each external cause by age, sex, country, and year. Survey data included recall of injuries that led to hospital admission and other levels of medical attention. The meta-regression included a covariate for whether an individual was admitted to hospital or not, which was used to generate predictions both for injury warranting hospital admission and injury warranting outpatient care. Second, negative binomial models were used to analyse hospital data from 28 countries that had dual coding of discharges by external cause and nature of injury after ICD-9 and ICD-10. This led to matrices of external codes and nature of injury categories by age and sex, for high-income and low/middle-income countries and separately for injuries that were treated in emergency departments and those that led to admission. Third, for each nature of injury the prevalence of short-term disability was estimated from incidence and expert estimates

of duration. Fourth, the probability of individuals developing long-term disability was estimated in a re-analysis of follow-up data from four rare studies in two high-income countries that documented outcomes of injuries after 1 year. Fifth, DisMod-MR was used again to estimate the prevalence of individuals in the population who have disability from a previous injury. Prevalence was estimated from incidence assuming zero remission and a relative risk of death compared with the general population based on available studies. In the last step, the YLDs due to prevalent cases of long-term injury were attributed back to external causes in proportion with the contributions of these causes to every type of injury.

14. Disability weights

DWs used in GBD 2010 have already been discussed in the earlier section on value choices.

15. Severity distributions

For 41 diseases, the sequelae of the disease have been linked to more than one health state (often classified as mild, moderate, and severe) including stroke, anxiety, major depressive disorder, dementia, and asthma. DWs across these severity levels were measured in population surveys for individuals without co-morbidity. Therefore, estimates of the distribution of severity need to be controlled for co-morbidity, otherwise the severity distribution would be systematically biased towards more severe symptoms. For example, if individuals with stroke are also likely to have diabetes and kidney disease, the reported distribution of functional health status would be shifted towards the more severe end.

For some diseases for which data are available for the distribution of severity by age, sex, and region, we pooled proportions in each health state using DisMod-MR or simple meta-analysis methods. Data for severity distributions are often scarcer and of poorer quality than data for prevalence of disorders. Because of the heterogeneity of the available evidence for disease severity, disease-specific reviews had to be supplemented with an analysis of three high-income country data sources which combined a range of diagnostic information and health status data. These sources allowed the assessment of the severity distributions, taking into account co-morbidity.

16. Co-morbidity simulation

In past GBD studies, YLDs were estimated for each disease and sequela and then simply added, implicitly assuming that disability from different conditions is additive. At the level of an individual this can lead to a person with several severe impairments having a combined level of DWs exceeding one, that is, being worse than dead. The 2003 Australian Burden of Disease study (Begg et al. 2008) introduced a method to simulate hypothetical populations with a correction for co-morbidity using a multiplicative rather than additive function to combine DWs. A similar approach was adopted for GBD 2010.

For each age, sex, country, and year, we used a Monte Carlo simulation of 20,000 individuals to estimate the co-occurrence of sequelae using the prevalence data with uncertainty intervals as probabilities. In simulated individuals with two or more sequelae a combined DW was calculated with a multiplicative function and then parsed back proportionately to each co-morbid sequela. The

mean reduction across all individuals with a particular sequela was taken as the co-morbidity correction.

Tests on real data from the US Medical Expenditure Panel Surveys (Agency for Healthcare Research and Quality 2000) suggested that this multiplicative model was the most appropriate and that after correcting for independent co-morbidity (i.e. just based on prevalence), taking further into account that some conditions are dependent (i.e. more likely to co-occur in the same individual) made little additional difference to the co-morbidity corrections.

17. Healthy life expectancy

The life tables developed in component 4 for each country and the output of the co-morbidity simulations were combined to estimate healthy life expectancy for 187 countries. Healthy life expectancy is a single summary metric of population health that is not affected by population age structure. It can be thought of as equivalent to the expectation of life at birth in full health given the currently observed age-specific death rates and prevalence of disease and injury sequelae.

18. Calculation of YLDs, YLLs, and DALYs

YLLs are simply the multiplication of the deaths by cause, age, sex, country, and year with the relevant value from the standard life table for the age at death. YLDs are the product of prevalence of a sequel and the co-morbidity-corrected DW. DALYs are the simple addition of YLLs and YLDs. Each quantity in GBD 2010 is estimated with uncertainty by generating 1000 draws. A thousand values of each summary measure are computed by taking the first draw for each quantity, then the second draw and so on until 1000 estimates are calculated. Thus, the correlation across age and over time for causes of death sequelae prevalence is retained.

19. Estimating risk factor exposure

In GBD 2010, risk factors were chosen based on their likely importance to disease burden or policy; availability of sufficient data and methods to enable estimation of exposure distributions by country; sufficient evidence for causal effect and to estimate outcome-specific effect sizes; and evidence to support generalizability of effect sizes to populations other than those included in epidemiological studies.

Analogous to the same principles used for work on disease sequelae, a database of published and unpublished sources on the prevalence of exposure was created. For some risks, innovative sources such as satellite imagery have been used. For a number of risk factors, primary survey data have been collated and re-analysed along with published studies.

20. Theoretical minimum risk factor distribution

The tradition in risk factor epidemiology is to assess attributable burden by estimating a counterfactual scenario where exposure to a risk factor in the past is set to a counterfactual distribution. Attributable deaths, YLLs, YLDs, or DALYs are then the difference between observed burden of disease and the counterfactual scenario. Following the framework for comparative risk assessment (Murray and Lopez 1999), counterfactuals are set to the lowest risk distribution that has been observed or is theoretically possible—the theoretical minimum risk exposure distribution.

21. Estimating relative risks for risk factor–disease pairs

For each risk–disease pair, relative risks for specific disease outcomes have been taken from published meta-analyses or updated meta-analyses that have been undertaken as part of GBD 2010. Special analyses have been undertaken for water and sanitation, all sources of particulates less than 2.5 microns, and the components of diet. Standardized approaches to the attenuation of relative risks with age for cardiovascular disease outcomes have been included. Uncertainty in the relative risks for each risk–disease pair by age and sex have been propagated into the final estimates. Full details on the risk factor estimation are provided in Lim et al. (2012).

22. Estimating deaths, YLDs, YLLs, and DALYs attributable to risk factors

Risk factor burden is assessed using the distributions of burden for each disease associated with a risk factor. Uncertainty from the prevalence of exposure, relative risks, and where appropriate the theoretical minimum risk exposure distribution, are all propagated into the final risk factor uncertainty. Final uncertainty reflects both the uncertainty for an age–sex group from the process of disease and injury estimation and the uncertainty in the population attributable fractions. We assume that uncertainty in the population attributable fractions is uncorrelated with uncertainty in disease and injury burden. For the computation of clusters of risk factors (e.g. diet), we have assumed that the combined effects of risk factors are multiplicative and independent.

Exploring GBD results

The GBD is considered a ‘public good’. To guide policymakers, researchers, students, and interested individuals through the large amount of results, IHME has created innovative visualization tools to explore health trends for different countries and regions. The visualization tools allow people to view GBD estimates through hundreds of different dimensions. To explore the IHME website to use the GBD data visualization tools, visit <http://www.healthmetricsandevaluation.org/gbd/visualizations/country>.

The *Mortality* and *Causes of Death* visualizations show the results, data inputs, and data transformations of all mortality estimates. *GBD Compare* shows results of deaths, YLLs, YLDs, and DALYs by diseases and risk factors. The main view is a ‘tree map’ which is basically a square pie chart showing the proportional distribution of the overall burden by underlying causes. Additional views can be added showing a map of the world, time plots, or age plots. Each can interactively be explored by country, age, sex, year, cause, or risk factor. Data are available as counts, rates, and proportions of total. Rates can be shown by age for all ages combined and age standardized to the 2001 WHO world standard population (Ahmad et al. 2001). The former is most useful to explore the amount of disease burden health systems need to address. The latter helps to understand the underlying epidemiological trends, that is, after taking out population growth and ageing as drivers of differences in burden estimates. *GBD Arrow Diagram* allows the user to compare ranking lists for countries and world regions between 1990 and 2010. As with *GBD Compare*, changes in ranking and rates can be viewed with and without age standardization.

GBD Cause Patterns is the tool of choice to compare country results with any grouping of other countries. It can also be used to explore age patterns. *GBD Heatmap* is a different method of showing rankings of diseases or risk factors between countries and regions of choice. Top ranking causes are coloured in deep red and successively shaded in lighter hues that change to yellow, green, and blue further down the ranking. This tool quickly shows areas of progress or concern in a particular country in comparison to others. The *GBD Uncertainty Visualization* tool graphically shows the width of the uncertainty intervals for quantities of interest and allows a quick scan of the importance of differences in ranks. The *Healthy Life Years vs Life Expectancy* tool graphs these two summary measures of population health and how they have changed over time for each country. Lastly, there is the *GBD Insight* tool which shows summary country profiles.

Key GBD results

A comparison of the top 20 causes of DALYs in the world between 1990 and 2010 shows a shift from communicable, maternal, neonatal, and nutritional disorders (dark blue) to non-communicable diseases (blue) and injuries (light blue) (Fig. 5.17.2). Ischaemic heart disease and stroke have become the leading and third-leading causes, displacing lower respiratory infections, diarrhoeal diseases, and pre-term birth complications. Among the major infectious diseases, only malaria and HIV/AIDS increased in rank and size. The growing importance of disability contributing to the burden of disease globally is illustrated by the prominent and rising positions of low back pain and major depressive disorder,

both responsible for large amounts of YLDs but no mortality (Fig. 5.17.2).

The column on the right of Fig. 5.17.2 shows the median proportion change in DALYs (with a 95 per cent uncertainty interval) between 1990 and 2010. Some of the change is due to population increase, some due to ageing of the world’s populations, and some due to a change in the epidemiological trends. Fig. 5.17.3 shows the same top-20 ranking of DALYs but based on age-standardized rates. In this figure the column on the right reflects the change in epidemiological rates over time having removed the demographic drivers of changes in the numbers of DALYs. Apart from a shift in the ranks of some conditions the greater difference is in the median proportion change column. For instance, the increase in stroke DALYs was entirely due to demographic changes, while the epidemiological rates actually dropped by 23 per cent, as seen in Fig. 5.17.3. Similarly, the DALYs for low back pain increased by 43 per cent, while the rate showed just a trivial change. Both measures have their own use. Changes in the volume of disease (as in Fig. 5.17.2) inform policymakers about health service planning. The epidemiological changes tell us something about the impact of prevention and cure on the occurrence of disease.

The shift from communicable diseases largely affecting children to non-communicable disease in adults is further illustrated by the change over time in the ranking order of the main risk factors (Fig. 5.17.4). Childhood underweight has been replaced by dietary risks (a combination of 14 component dietary factors such as low fruit or vegetable intake or high sodium intake). High blood pressure and high body mass (overweight and obesity) have increased in rank and amount of disease burden. The small overall

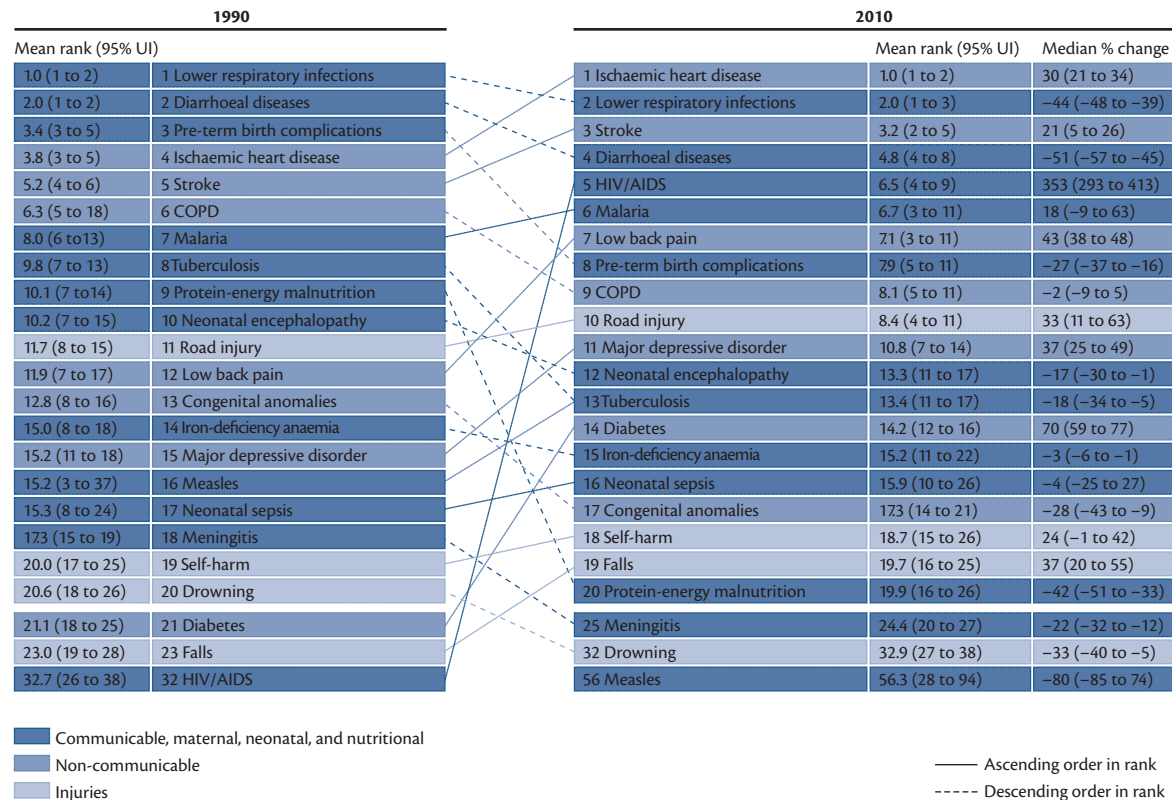

Fig. 5.17.2 Global top-20 ranking of diseases and injuries in DALYs, 1990 and 2010.

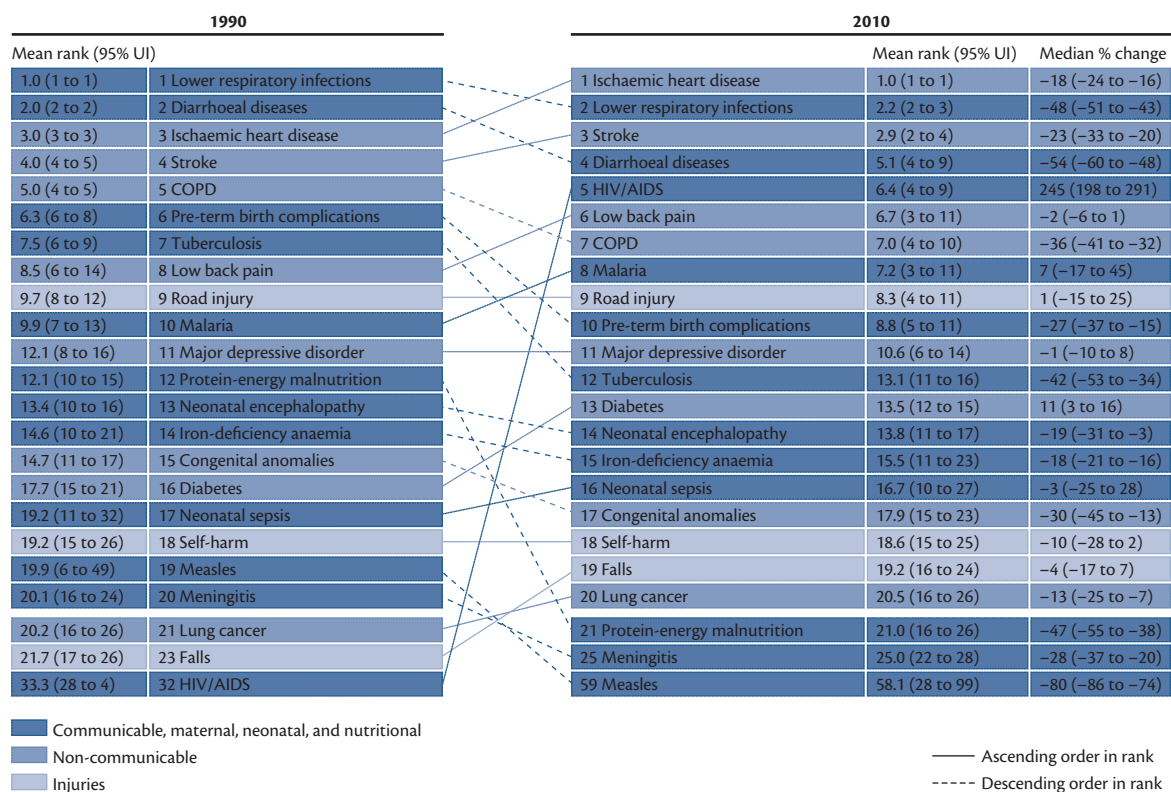

Fig. 5.17.3 Global top-20 ranking of diseases and injuries in age-standardized DALY rates, 1990 and 2010.

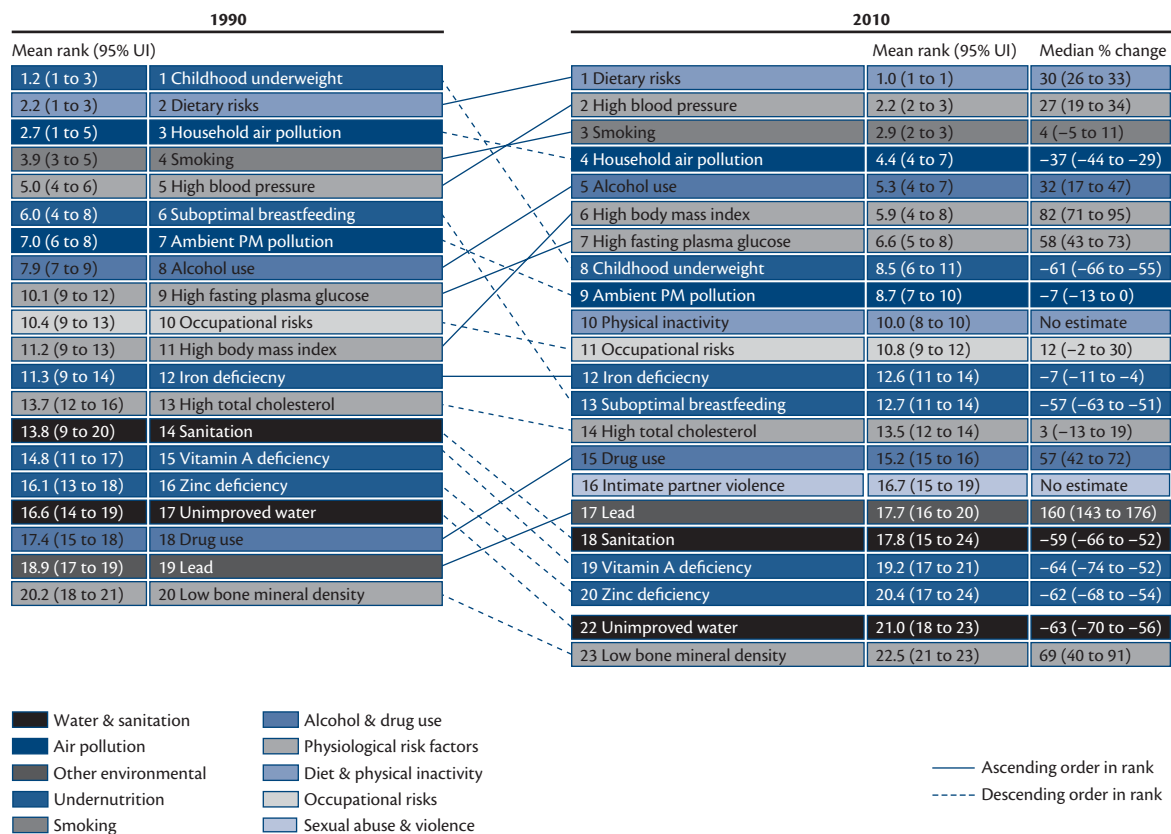

Fig. 5.17.4 Global top-20 ranking of risk factors in DALYs, 1990 and 2010.

change in burden from smoking masks an increase in low- and middle-income countries being compensated by a slowly decreasing burden from smoking in high-income countries.

The future of GBD

GBD will be updated annually. The intention is to expand the network of collaborators to include country researchers, staff of ministries of health, and IHME to strengthen national estimates and to undertake subnational burden of disease studies. Local epidemiological assessment is crucial for informing local priorities.

IHME is seeking partners interested in conducting in-depth studies of the burden of disease in countries. Through such partnerships, IHME is helping governments and donors gain insights into localized health trends to inform planning and policymaking. IHME is committed to building capacity for GBD analysis in countries around the world, and will be conducting a variety of training workshops. Information on training can be found at <http://www.healthmetricsandevaluation.org/gbd/training>.

Currently, IHME is working to expand GBD to track expenditure for particular diseases and injuries. Also, IHME is estimating utilization of outpatient and inpatient facilities and other health services for specific diseases and injuries. Side-to-side comparisons of these estimates to the number of DALYs from myriad causes will allow decision-makers to better evaluate health system performance and priorities.

Mathematical models of transmission and control of infectious agents

Alex Welte, Brian Williams, and Gavin Hitchcock

Introduction to mathematical models of transmission and control of infectious agents

Mathematical modelling plays a key role in the design, implementation, and evaluation of public health interventions. Here we clarify what mathematical modelling is, show how it has been used successfully in the past, and discuss ways in which it can be used to interpret epidemiological trends and project trends into the future.

It is important at the outset to distinguish between static models, which often rely on sophisticated statistical analyses, and dynamical models, which more often depend on computer-based simulations. The recurrent theme in dynamical modelling, which is the focus of this chapter, is the interplay between what can be known about the nature and course of an infection in an individual, and what can be known about disease trends in a community. It is remarkable that it is possible to move between these scales at all; but the beauty of mathematics is that it allows us to capture fundamental patterns and relations between rates and numbers. These may be the rates at which people are born, die, become infected, are cured, or recover; and the numbers of people in different classes, age groups, or stages of infection. Einstein observed that ‘the supreme goal of all theory is to make the irreducible basic elements as simple and as few as possible without having to surrender the adequate representation of a single datum of experience’ (Einstein 1934); that is, for modellers: always start with the simplest possible assumptions and the smallest number of parameters, adding complexity only where provoked and justified by specific data or key hypotheses about cause and effect, seeking always to bring to light the essential underlying patterns and the dominant processes and mechanisms.

While epidemiological data can be collected among individuals, and clinical trials can measure the response of individuals to different treatments or interventions, public health is usually concerned with the dynamics of disease over time, in specified population groups, under varied conditions, and under different interventions. In public health, many factors—biological, psychological, sociological, and economic—are involved in understanding what is likely to work, how people will respond, whether an

intervention will be acceptable, how much it will cost, and what the impact is likely to be. Models are now being used not only to understand the natural history of disease but also to advise and guide public health policy and resource allocation. Mathematical modelling has become an indispensable part of public health.

The uses of models in public health are many and varied, both as concerns the nature of the models and the range of the problems to which they are applied. Good recent introductions to modelling infectious diseases are by Bacaër (2010), Vynnycky and White (2010), Brauer et al. (2008), and Keeling and Rohani (2008). Models have become important, especially in contexts where good empirical data are not readily available, for predicting changes over time in disease burden and treatment requirements, hence warranting projections of counterfactuals in quasi-experimental impact evaluation designs, and power calculations for experimental study designs (Delva et al. 2012). Recent applications include determining optimal responses to emerging pathogens (Riley et al. 2003), clarifying the requirements for eradication of polio (Grassly et al. 2006), exploring the impact of control measures and quantifying uncertainty in predictions for influenza pandemics (Fraser et al. 2009; Keeling and Danon 2009), evaluating intervention strategies for malaria (Griffin et al. 2010), and re-evaluating investment strategies in HIV programmes (Salomon et al. 2005; Granich et al. 2009; Schwartländer et al. 2011). The unprecedented attention and funding which the HIV/AIDS epidemic has attracted has brought infectious disease modelling to prominence in this field. Increasing reliance on mathematical modelling has been shown by agencies which fund, coordinate, and evaluate HIV prevention efforts: the World Bank, the Global Fund, the World Health Organization (WHO), the United Nations Joint Programme on HIV and AIDS (UNAIDS), and the President’s Emergency Plan for AIDS Relief (PEPFAR). Lately, while spending on HIV has levelled off and might even be declining (Kaiser Family Foundation 2011), some important discoveries have been made, notably that antiretroviral therapy (ART) can dramatically reduce infectiousness in HIV-positive individuals (Cohen et al. 2011). The many questions that this provokes, and in particular the extent to which early treatment can stop the epidemic of HIV, can be approached most effectively by mathematical modelling

(Montaner et al. 2006; Granich et al. 2009; Delva et al. 2012). Examples include: (1) how funding should be reallocated in the light of new data (Granich et al. 2009), (2) deciding the importance or otherwise of the acute phase of HIV infection in the dynamics of the epidemic (Cohen et al. 2012), (3) how to evaluate the threat of drug resistance to the effectiveness of treatment (Wagner et al. 2010), and (4) how best to measure the impact of existing programmes (Hallett et al. 2007).

Brief historical overview

Perhaps the first application of dynamical mathematical modelling in public health was carried out in 1760 by Daniel Bernoulli to understand the efficacy of inoculating people with smallpox to prevent their developing the disease later. Bernoulli used what we would now call an ‘SR model’ (of susceptible and removed elements) to elucidate the variations in the size of susceptible and removed subpopulations over time (Bernoulli 1760/2004; Dietz and Heesterbeek 2002; Bacaër 2010). Bernoulli concluded that, while inoculation carried some risk, it could substantially increase life expectancy, not only by trading the risks and benefits for individuals but (crucially) also by reducing overall transmission in the population.

More than one hundred years after Bernoulli’s seminal work, Ronald Ross showed in 1895 and 1899 that malaria infects people through the bites of mosquitoes, and for this discovery he was awarded the Nobel Prize for Physiology or Medicine in 1902. In fact, Ross may have been a better mathematician than he was an entomologist. He developed one of the first mathematical models of disease transmission based on differential equations to support his claim, in the face of considerable scepticism, that malaria could be eradicated by reducing the mosquito population to below a critical level. The notion that there are critical thresholds on dynamical parameters, below which disease transmission cannot persist, could be called ‘the central dogma of epidemiology’. This is most famously embodied in the concept of R_0 , the basic reproduction number, about which there is more later in this chapter. A crucial example of such a ‘tipping point’, which can only be understood through the collective dynamics of a population, is the attainment of ‘herd immunity’ at partial coverage of an imperfect vaccine—that is, the effect that, while there are still infected and susceptible individuals in a population, the prevalence is doomed to decline if transmission is not efficient enough to replace cases as quickly as they are naturally removed (see online appendix for more details).

Ross’s model, published in the second edition of his book *The Prevention of Malaria* (Ross 1910, 1923), became the basis for subsequent modelling of vector-borne infections and is a good illustration of how such a mathematical model is formulated. It consists of two differential equations expressing the rates of change of I (the number of infected humans) and i (the number of infected mosquitoes), in terms of I , i , N (the total human population in the area of concern), and a few other parameters. Ross’s work and later developments have been discussed in detail by Smith et al. (2012). Ross made a number of explicit assumptions, encapsulated in the constancy of the parameters: the total number of mosquitoes n ; the biting frequency of mosquitoes b ; the transmission probabilities p , and p' , per bite, of malaria, from mosquito to human, and vice versa; the rate a at which humans recover from malaria; and

the mortality rate m of mosquitoes. This model implies a relationship between malaria prevalence, I/N , and the ratio of numbers of mosquitoes to humans, n/N . There is a critical threshold value for this ratio, below which prevalence tends to zero in the long run, and above which the endemic prevalence of infection in people would increase rapidly, before beginning to level off at about 50 per cent. Importantly, this levelling off helps to explain how it was that no correlation had been previously observed between mosquito numbers and malaria prevalence. While the threshold itself is very sensitive to changes in the biting rate b , Ross observed that the basic overall shape of the curve does not change. He concluded, as cited in Bacaër (2010):

As a matter of fact all epidemiology, concerned as it is with the variation of disease from time to time or from place to place, must be considered mathematically, however many variables are implicated, if it is to be considered scientifically at all. To say that a disease depends upon certain factors is not to say much, until we can also form an estimate as to how largely each factor influences the whole result. And the mathematical method of treatment is really nothing but the application of careful reasoning to the problems at issue.

In the late 1920s and 1930s, William Kermack and Anderson McKendrick introduced continuous-time epidemic models that incorporated stochastic (random) elements of infection and recovery (McKendrick 1926; Kermack and McKendrick 1927; Harvey 1943; Bacaër 2010). They showed how to include age or time since infection as continuous variables, and how to generalize models to deal with time-dependent infectiousness and recovery rates. Together with Hamer, Soper, and Ross, they laid the early foundations for modern mathematical modelling in epidemiology. Crucially, they realized that epidemics are driven by the rate of contact between susceptible and infectious individuals. Because the simplest models do not distinguish between individuals, all uninfected people are equally likely to be infected and the probability that a susceptible person is infected is simply proportional to the number of people who are already infected. The so-called principle of mass-action, first formulated to model the rates of chemical reactions, now found applications in infectious disease epidemiology. It simply captures the idea of two populations being so perfectly mixed that the ‘contact rate’ is proportional to each population size individually.

A major theme in twentieth-century modelling was analysing the existence and implications of critical thresholds, already introduced above. When considering the control of transmissible diseases, the single most important concept is the basic reproduction number, conventionally written as R_0 and most commonly thought of as the number of secondary cases produced by a single primary case introduced into an otherwise entirely uninfected population. The roots of this concept can be traced through the work of Alfred Lotka, Ronald Ross, and others, but its first modern application in epidemiology was by George Macdonald (1957), in constructing population models of the spread of malaria. The concept was extended and developed by Dietz (1980) and by Anderson and May (1991) and their various colleagues and co-workers. The collaboration of Anderson and May culminated in their definitive book *Infectious Diseases of Humans: Dynamics and Control* (1991).

The last decade has seen dramatic developments in the role of modelling in informing public health policy and funding decisions. This may be illustrated by two reviews of modelling in the context of HIV, the first, by Stover in 2000, exhorting, and the

other, by Johnson and White in 2011, almost exulting, while still urging better modelling practice and clarity in communication:

Better mechanisms to translate modelling results into information that is usable by policy makers are needed to enhance the impact of modelling research on HIV and AIDS policies and programs. (Stover 2000)

Mathematical models can assist policy makers in comparing the relative impact and cost-effectiveness of different interventions, generalising the results of randomised controlled trials to the local setting, identifying threats to programme success, identifying opportunities for maximizing intervention impact/efficiency and evaluating the extent to which observed trends in HIV prevalence are attributable to HIV/AIDS programme success. (Johnson and White 2011)

A number of other reviews of modelling in epidemiology have recently been published (Grassly and Fraser 2008; Temime et al. 2008; Keeling and Danon 2009; Garnett et al. 2011; Wilson and Garnett 2011; Eaton et al. 2012). While the proportion of published papers on epidemiological modelling, recorded in the Web of Science database, roughly quadrupled from 2000 to 2010, the growth in citations of this work has not been commensurate, notwithstanding the third bullet point below, which relates to a particular subfield. This highlights the need to make epidemiological modelling more accessible to a wider audience (see Box 5.18.1). In an interesting review, ‘The rising impact of mathematical modelling in epidemiology: antibiotic resistance research as a case study’ (Temime et al. 2008), the authors found:

- ◆ ‘A general interest in applied mathematical epidemiological models outside the fields of mathematics or epidemiology.’

Box 5.18.1 Basic concepts crucial to the modelling of infectious agents (see online appendix for more detailed discussion)

- ◆ *(Disease) mortality*: rate of death (usually probability per year).
- ◆ *Basic reproduction number*: number of new cases directly produced by one case in a purely susceptible population.
- ◆ *Case detection rate*: proportion of cases detected (within a time frame), or probability per unit time of detection.
- ◆ *Disease duration*: length of time individuals spend in an infected state.
- ◆ *Epidemic growth rate*: (usually relative) growth rate of prevalence.
- ◆ *Equilibrium*: a scenario in which the state of the model world is unchanged by time.
- ◆ *Herd immunity*: collective ability of a population to resist or extinguish an outbreak, despite containing susceptible individuals.
- ◆ *Incidence*: rate of occurrence of infections.
- ◆ *Initial doubling time*: time taken for an early prevalence to double.
- ◆ *Model scenario*: ‘model world’ history with fully specified initial conditions and rules.
- ◆ *Parameter*: a variable which expresses a rule—a model input.
- ◆ *Prevalence*: proportion of a population affected by a condition at a point in time.
- ◆ *State variable*: a variable capturing a model output.

- ◆ ‘Heightened attention and acceptance accorded to these methods (modelling) by the scientific community.’
- ◆ A ‘high citation impact... for most modelling articles, compared to other articles published in the same journals’ (Temime et al. 2008).

What is a mathematical model?
